## GENERAL INSTRUCTIONS FOR COMPLETING SF 298

The Report Documentation Page (RDP) is used in announcing and cataloging reports. It is important that this information be consistent with the rest of the report, particularly the cover and title page. Instructions for filling in each block of the form follow. It is important to *stay within the lines* to meet *optical scanning requirements*.

**Block 1. Agency Use Only (Leave blank).**

**Block 2. Report Date.** Full publication date including day, month, and year, if available (e.g. 1 Jan 88). Must cite at least the year.

**Block 3. Type of Report and Dates Covered.**

State whether report is interim, final, etc. If applicable, enter inclusive report dates (e.g. 10 Jun 87 - 30 Jun 88).

**Block 4. Title and Subtitle.** A title is taken from the part of the report that provides the most meaningful and complete information. When a report is prepared in more than one volume, repeat the primary title, add volume number, and include subtitle for the specific volume. On classified documents enter the title classification in parentheses.

**Block 5. Funding Numbers.** To include contract and grant numbers; may include program element number(s), project number(s), task number(s), and work unit number(s). Use the following labels:

<b>C</b> - Contract	<b>PR</b> - Project
<b>G</b> - Grant	<b>TA</b> - Task
<b>PE</b> - Program Element	<b>WU</b> - Work Unit
	Accession No.

**Block 6. Author(s).** Name(s) of person(s) responsible for writing the report, performing the research, or credited with the content of the report. If editor or compiler, this should follow the name(s).

**Block 7. Performing Organization Name(s) and Address(es).** Self-explanatory.

**Block 8. Performing Organization Report Number.** Enter the unique alphanumeric report number(s) assigned by the organization performing the report.

**Block 9. Sponsoring/Monitoring Agency Name(s) and Address(es).** Self-explanatory.

**Block 10. Sponsoring/Monitoring Agency Report Number. (If known)**

**Block 11. Supplementary Notes.** Enter information not included elsewhere such as: Prepared in cooperation with...; Trans. of...; To be published in.... When a report is revised, include a statement whether the new report supersedes or supplements the older report.

**Block 12a. Distribution/Availability Statement.**

Denotes public availability or limitations. Cite any availability to the public. Enter additional limitations or special markings in all capitals (e.g. NOFORN, REL, ITAR).

**DOD** - See DoDD 5230.24, "Distribution Statements on Technical Documents."

**DOE** - See authorities.

**NASA** - See Handbook NHB 2200.2.

**NTIS** - Leave blank.

**Block 12b. Distribution Code.**

**DOD** - Leave blank.

**DOE** - Enter DOE distribution categories from the Standard Distribution for Unclassified Scientific and Technical Reports.

**NASA** - Leave blank.

**NTIS** - Leave blank.

**Block 13. Abstract.** Include a brief (*Maximum 200 words*) factual summary of the most significant information contained in the report.

**Block 14. Subject Terms.** Keywords or phrases identifying major subjects in the report.

**Block 15. Number of Pages.** Enter the total number of pages.

**Block 16. Price Code.** Enter appropriate price code (*NTIS only*).

**Blocks 17. - 19. Security Classifications.** Self-explanatory. Enter U.S. Security Classification in accordance with U.S. Security Regulations (i.e., UNCLASSIFIED). If form contains classified information, stamp classification on the top and bottom of the page.

**Block 20. Limitation of Abstract.** This block must be completed to assign a limitation to the abstract. Enter either UL (unlimited) or SAR (same as report). An entry in this block is necessary if the abstract is to be limited. If blank, the abstract is assumed to be unlimited.

## ABSTRACT

LONG-DURATION EXPOSURE CRITERIA FOR HEAD-SUPPORTED MASS by  
MAJ(P) Barclay P. Butler, USA, 69 pages.

The modern crew station of Army helicopters uses the helmet as an integral component of the aircraft control systems. What was once viewed as a simple device for crash protection now supports devices including night vision goggles, chemical mask, head-up displays, and weapon aiming systems. These devices combine to increase the biomechanical stress in the neck. This study investigated the effects of increasing helmet torque on the motion of the helmeted head under the conditions of long-duration whole-body vibration exposure.

Twelve U.S. Army volunteer aviators were exposed to four hours of whole-body vibration, similar to that found in a UH-60 helicopter, while wearing four different helmets. Helmet torques, as calculated at the point where the head connects to the spine, ranged from a standard aviator helmet to a helmet with a chemical mask and a night vision goggle. Head motion was measured using a three dimensional active infrared marker system attached to a fixture held in the subject's teeth.

Results showed no significant differences ( $p < 0.05$ ) in head pitch motion over time for helmets, but significant differences among helmet torques. These results support the existing recommended helmet design of limiting the added helmet torque to 90 N·cm for long-duration helicopter flights.

#### ACKNOWLEDGEMENTS

I wish to acknowledge the efforts of the personnel at the United States Army Aeromedical Research Laboratory, Crew Injury Division, Response and Tolerance Branch, located at Fort Rucker, Alabama, for their efforts in generating the human response data I used for this thesis. Specifically, I would like to thank Dr. Nabih Alem for his efforts in managing the completion of the data acquisition phase of the experiment when I was transferred from the laboratory to a new assignment. Dr. Alem was also responsible for archiving the data and making it available to me for analysis during my tour at Fort Leavenworth. SSG Brad Erickson was responsible for managing the technicians during the data acquisition phase. He was able to keep three separate primary investigators satisfied, all whom wanted data from different aspects of the experiment. SSG Erickson was also quite useful in digging up the bits and pieces of information that are invariably required to complete the writing for any research effort. Mr. Al Lewis, the senior design engineer for this project, was responsible for designing and implementing the control system managing the data acquisition. His management of his staff to provide technical operators for the Multiaxis Ride Simulator allowed us to complete this effort in the most efficient manner. Finally, I would like to thank Mrs. Mary Gramling for her efforts in editing the research proposal, and managing the office requirements keeping the paperwork straight. Without these people this project would never have materialized. I am deeply indebted to them for their efforts.

## CHAPTER 1

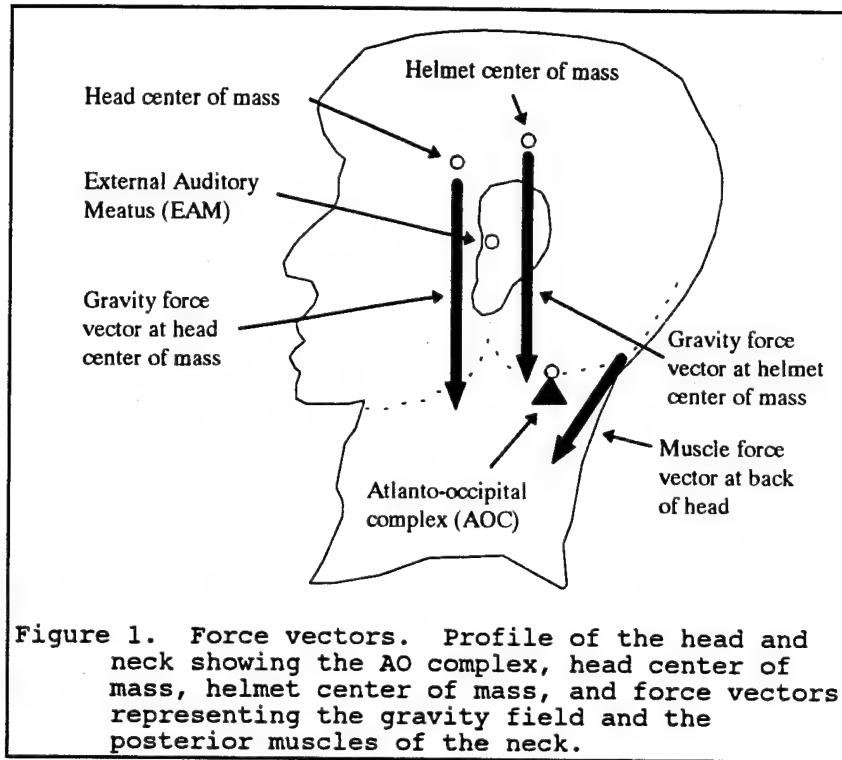

### INTRODUCTION

The modern crew station of Army helicopters uses the helmet as an integral component of the aircraft control systems. What was once viewed as a simple device for crash protection, the helmet has evolved into an equipment mounting platform. Aviator helmets now support numerous combinations of devices including night vision goggles, chemical mask, oxygen system, head-up display, forward looking infrared display, flash blindness and laser eye protection, and weapon aiming systems. All these devices add to the weight of the helmet, which in turn contributes to increased biomechanical stress in the muscles of the neck that are responsible for controlling head motion.

Helmet weight can be characterized by its mass and center of mass. Mass is a concept that describes an object's resistance to acceleration and is proportional to an object's weight.<sup>1</sup> The higher the mass of an object the greater the resistance the object has to acceleration. An object's center of mass is a concept that describes the single location, or point in space, where all of the moments acting on the object sum to zero.<sup>2</sup> Conceptually, this is similar to the idea of balancing an object on a knife-edge. Here the forces that attempt to rotate the object in one direction are counterbalanced by the forces that attempt to rotate it in the other direction. The concept of center of mass extends this idea to three dimensions and uses forces and moments in all directions, not just in the direction of gravity.

The helmet mass and center of mass combine to create a torque that must be counterbalanced by the muscles in the back of the neck to maintain an upright posture. The head, too, creates a torque that attempts to rotate the head moving the chin downward towards the chest.

The torques from the helmet and the head combine to create a torque that is larger than the torque due to the head alone. The pivot point through which this torque operates is on top of the cervical spine and is known as the atlanto-occipital (AO) complex.<sup>3</sup> Figure 1 shows the head, the location of the AO complex on top of the cervical spine, and the locations of the head center of mass and the helmet center of mass. Force vectors are also shown located at each center of mass. These force vectors must be counterbalanced by the muscles in the back, or posterior, of the neck.

The amount of torque that must be counterbalanced by the posterior neck muscles depends on the mass of the head and helmet and on the distance these centers of mass are from the AO complex. Head mass is considered a constant at about 4.2 kg. Helmet mass, however, can change, either from the introduction of new helmet designs, or more readily, through the attachment of devices to the helmet itself. These

devices, such as those mentioned above, are typically added to the front of the helmet to aid in vision, filter air, or add ballistic or eye protection, just to name a few. The masses of these devices also add to the helmet and head mass resulting in another increase in torque around the AO complex. This situation can continue to progress to a point where the total head-supported mass creates a torque that is more than the posterior neck muscles can effectively control.

The total head-supported mass is not the only factor affecting the stress on the posterior neck muscles. Changes in head posture can change the effective length of the lever arm connecting the helmet center of mass to the AO complex as initially shown in figure 1. For example, by rotating the head so the face points upwards, the force vectors are moved towards, and sometimes past, the AO complex (figure 2). This reduces the torque that the neck muscles must support.

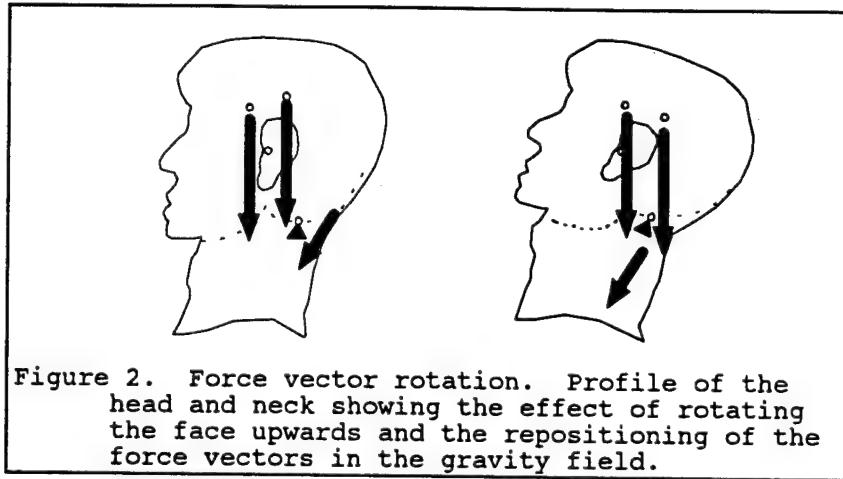

Figure 2. Force vector rotation. Profile of the head and neck showing the effect of rotating the face upwards and the repositioning of the force vectors in the gravity field.

The presence of whole-body vibration, as is always true in a helicopter, causes the head to pitch up and down.<sup>4</sup> This pitching motion causes an involuntary stretch response in the posterior muscles of the neck that further increases the amount of force produced by these muscles. The duration of a helicopter flight requires the posterior muscles of the neck to exert counterbalancing forces for a greater

period of time than required under more natural conditions. These factors affect the amount of biomechanical stress experienced by the posterior neck muscles, and play a role in determining a reasonable head-supported mass limit for Army rotary-wing aviators.

The identification of a limit for head-supported mass was a recent topic of research undertaken at the U.S. Army Aeromedical Research Laboratory (USAARL).<sup>5</sup> In this study, volunteer aviators were exposed to different helmet torques while experiencing simulated UH-60 helicopter vibration for twenty-minute periods. Results showed that the motion of the combined head and helmet was not different from the motion of the head alone when the total head-supported torque was less than 90 Newton-centimeters (N·cm) measured relative to the AO complex. The practical application of these results indicates that using the modern night vision goggles with the batteries as a counterbalance is satisfactory, but flying with a chemical mask will stress the posterior neck muscles. While this is a significant first step in specifying limits for head-supported mass, there is a need to extend this criterion to be applicable for longer duration exposures (four hours) that more nearly approach actual operational flight times experienced by Army rotary-wing aviators.

More recently, USAARL researchers completed the data acquisition phase of experiments addressing head-supported mass under long-duration whole-body vibration exposure.<sup>6</sup> This thesis will use the experimental results from USAARL to test the hypothesis that under simulated UH-60 helicopter whole-body vibration there will be no change in head motion resulting from either (a) exposure duration, or (b) the magnitude of the head-supported mass. It is the purpose of this thesis to perform this analysis, apply the results to the initial head-supported mass criteria, and develop a more robust helmet design recommended practice for Army aviation.

### Study Significance

The significance of this study will be to extend the existing recommended practice for Army aviator head-supported mass criterion to include long-duration exposures. This updated criterion will be applied to the Comanche helmet program and will specify a recommended practice for all future aviation helmet procurement strategies. Operationally, an updated head-supported mass criterion will improve aviation safety by reducing aviator fatigue, ensuring modern helmet systems are constructed with an appreciation of the biomechanics of the human head and neck.

### Limitations and Delimitations

The primary limitations of this study involved the desire to maintain a high level of subject safety by minimizing the exposure time to large magnitude head-supported mass under whole-body vibration conditions. As such, only twelve subject were incorporated into the study, and exposure durations were limited to four hours for any one session. A secondary limitation was the inability to analyze the electromyographic data from the posterior neck muscles. This analysis was not performed due to time constraints imposed by the Master of Military Art and Science (MMAS) program. The electromyographic data would have been useful in determining the presence of muscle fatigue both over time and as a result of the magnitude of head-supported mass.

The delimitations of this study necessarily arose out of a desire to obtain reliable results with as small a subject pool as was practical. One method of achieving these results was to use a homogenous subject population. As a result of this approach, this study did not address head-supported mass for female aviators, nor did it address the very large or very small male aviator. Also, in-flight biomechanical performance was not assessed, nor was aviator flight maneuver performance, cognitive performance, or other psychophysical performance characteristics.

## CHAPTER 2

### REVIEW OF LITERATURE

The literature supporting this research effort falls into two broad and separate areas: (1) studies involving acute and chronic exposure effects of whole-body vibration, and (2) studies involving head motion during impact events similar to that experienced during automobile crashes. The area addressing whole-body vibration exposure effects is further split into two subareas. The first of these addresses the biomechanical effects of whole-body vibration exposure. This area is interesting in that it lays the groundwork for understanding vibration transfer to the head and neck. It also sets the stage for understanding acute effects of whole-body vibration with specific applications to skeletal muscle responses. However, there are only a few studies that actually address head motion under whole-body vibration, and only one that addresses helmeted head motion in this environment. The studies involving chronic exposure to whole-body vibration are geared to understanding disease effects. These have little applicability to this effort and will, therefore, not be addressed.

The second body of literature involves head impact studies. These are most useful in showing just what whole-body vibration exposure is not. For example, head motion arising from an automobile crash occurs so rapidly that there is no time for even reflexive neck muscle responses.<sup>7</sup> In contrast, head motion arising from whole-body vibration involves relatively static responses where the muscles of the neck are actively involved in maintaining posture and in reacting to vibration disturbances. Nevertheless, this body of work was pioneering in developing the instrumentation used in head motion studies. It will,

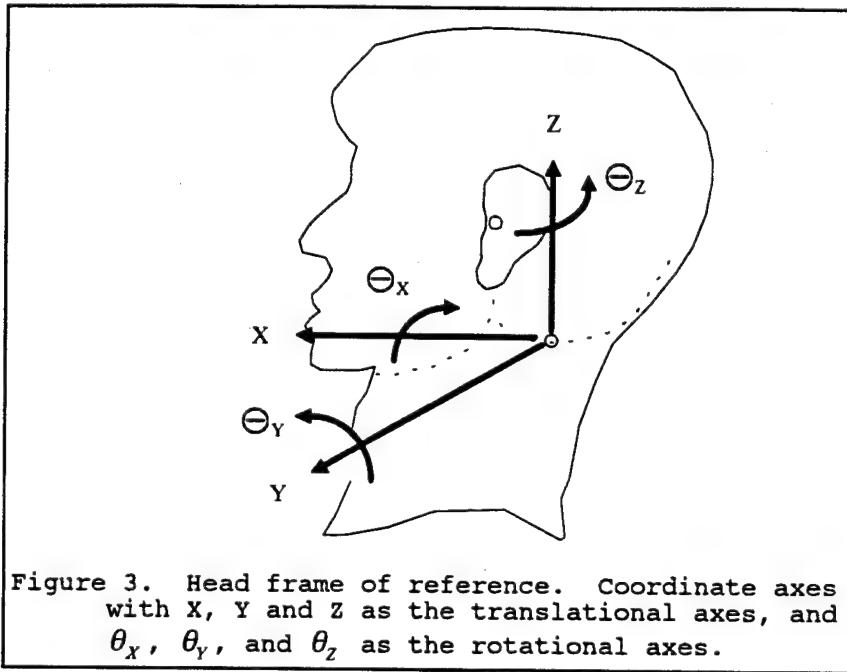

therefore, be cited in the research methodology section of this thesis to refer to specific instrumentation procedures.

#### Biomechanics of Whole-Body Vibration Exposure

Early work in whole-body vibration began with testing geared toward discovering the nature of vibration transfer through the body.<sup>8</sup> Of particular interest was determining how much energy was absorbed by the body. Energy transfer measurements were made on inert devices to test for their vibration stability. To perform this measurement, first the source of the vibration was measured. This would be known as the input vibration. Next, the result of the vibration transfer through the object would be measured. This would be the output vibration. The absorbed vibration would then be the difference between the input and output vibration levels. To perform these experiments on human subjects, volunteers were asked to sit on a seat attached to a vertical, or Z-axis, aligned platform that would vibrate back and forth in a sinusoidal fashion. Acceleration measurements were made using accelerometers attached to the hard underside of the seat pan to capture the input vibration, and from the top of the subject's head to capture the output vibration. The vibration platform would be excited at discrete frequencies ranging from two to forty cycles per second, or hertz (Hz). In calculating the transfer functions by dividing the output by the input, a dominant peak was found near 5 Hz with the output vibration nearly twice as large as the input vibration. This peak is an example of resonance, that is, a condition under which a cyclic input function results in an output that is larger than the input. This crude but effective technique set the stage for further refining whole-body resonant frequencies and for identifying resonant frequencies for body segments as well as specific organ systems.

These techniques were extended from single Z-axis measurements to multiple axis measurements at the head. The coordinate system for the head is shown in figure 3. Here the Z-axis, or the axially aligned

axis, is oriented vertically with the positive axis oriented upwards. The X-axis is oriented front to back, or anterior to posterior (AP), with the positive axis aligned forward. The Y-axis is oriented laterally with the positive axis aligned to the left. These axes are aligned in a right handed coordinate system. Figure 3 also shows the rotational axis of pitch, yaw, and roll.

Multiaxis vibration measurements of the head were first reported by Griffin for sinusoidal vertical vibration.<sup>9</sup> Griffin used linear accelerometers connected to a fixture, or bite bar, held between the teeth to measure head acceleration. He found that the predominant head vibration was in the Z-axis, followed by the X-axis, and then the Y-axis, the latter two showing less than 20 percent of the Z-axis vibration levels. These data indicated that the head moved in a vertical fashion for vertical input vibration. Considering that helicopter vibration is predominantly vertical, this would suggest that vertical head motion would be the most significant motion for the helmeted aviator.

In a subsequent effort, Griffin studied the effect of posture on vibration transmitted to the head.<sup>10</sup> He first asked the subject to sit in a posture that was most comfortable, and then sit in a posture where vibration transmitted to the body was the least comfortable. He showed that when subjects were in an upright posture with their spines aligned with the vibration axis, they reported the most uncomfortable condition. The most comfortable condition was noted when their spines were far out of the vibration axis. It is interesting to note that the preferred UH-1 Huey pilot posture is leaning forward, not upright. This result also has implications for experimental studies indicating that posture must either be controlled or measured to account for variations in transmitted vibration.

#### Skeletal Muscle Response to Whole-Body Vibration Exposure

Interest arose in investigating the effects of vibration exposure on skeletal muscle response. Matthews began an investigation using isolated muscle preparations and applying vibrating probes directly to the stretched tendons.<sup>11</sup> He showed that sinusoidal vibration resulted in a sinusoidal electrical burst response in the muscle, indicating a contraction-coupling reaction that was synchronized with the vibration frequency. He also demonstrated that random vibration stimulation did not show the sinusoidal burst pattern, but rather a complex burst pattern again related to the vibration signal. He theorized that the stretch response in the muscle was dependent upon the velocity of the stretching, which was consistent with his experimental data. These results are interesting in that helicopter vibrations can be characterized as a set of sinusoids related to the frequency of the main rotor blade passing by a given point.

Wilder, and others, extended Matthews' isolated muscle work by studying electromyographic (EMG) signals--the electrical signals generated by muscles during contraction--from volunteer subjects exposed to sinusoidal vibration.<sup>12</sup> Wilder, and others, placed sensing surface

electrodes over the paraspinal muscles of the lower back and measured input vibration at the seat pan, and output vibration at the top of the head. They asked volunteer subjects to maintain different postural angles for thirty-minute periods while exposed to sinusoidal whole-body vibration. They verified the results of Griffin that postural changes affected transmitted vibration, and also showed paraspinal muscle fatigue using measures of EMG median spectral shift. Their results indicated that vibration induces muscle fatigue more quickly than in a nonvibrated control group, and that muscle fatigue could be measured in a vibration environment using spectral analysis techniques on the EMG signals.

#### Head Motion Due to Whole-body Vibration Exposure

Detailed studies of head motion under whole-body vibration began with Sandover in 1978.<sup>13</sup> He combined the techniques of mounting an axially aligned accelerometer to a bite bar, and to the top of the head. He showed that the two accelerometers yielded dramatically different levels of axial acceleration, with the bite bar accelerometer showing more axial vibration than the head-mounted accelerometer. He concluded that the pitch motion of the head had caused the apparently larger axial response from the bite bar accelerometer as compared to the head mounted accelerometer. These data suggest that the pitch motion of the head may be the dominant response to axial vibration, and axial head motion maybe a secondary response. Also, understanding the relationship between the location of the accelerometer (or other transducers) and the dynamics of the underlying motion is critical to obtaining accurate head motion results.

Paddan and others were the first to report multiaxis measurements of head motion due to vertical whole-body vibration.<sup>14</sup> Using multiple accelerometers attached to a bite bar, they were able to capture all six axes of motion as shown in figure 3. Their results indicated that head pitch motion was the predominant vibration, followed

by Z-axis motion, and then X-axis motion. Very little motion was seen in the Y, yaw, or roll axes. This indicates that axial vibration results in a planar response for head motion with the dominant axes being in the axial, AP, and pitch directions. That is, head motion is confined to the midsagittal plane, or a vertical plane lying between the eyes.

The head motion measuring techniques developed by Paddan and others were employed by Butler to make detailed measurements of the helmeted aviator exposed to short duration sinusoidal Z-axis vibration.<sup>15</sup> Using twelve different helmet configurations (three mass and four center-of-mass parameters), he showed that there were significant differences in head pitch acceleration when the weight moment of the helmet exceeded 90 N·cm of torque measured relative to the AO complex. Using EMG measurements of the trapezius muscle at the back of the neck, Butler also showed significant increases in myoelectric activity when the helmet exceeded this 90 N·cm criteria.

In summary, axial whole-body vibration, similar to that found in helicopters, results in head motion confined to the midsagittal plane. The predominant head motions are pitch, axial, and AP responses, in that order. Myoelectric responses from the posterior neck muscles show burst responses that are synchronized with the vibration response. Muscle fatigue is indicated when the myoelectric responses show median spectral frequency shifts to lower frequencies, and/or increases in myoelectric peak magnitudes.

## CHAPTER 3

### RESEARCH METHODOLOGY

Describing the effects of head-supported mass on aviator performance is a complex task requiring a multidisciplinary approach. In addressing this problem, the USAARL designed a research protocol investigating the effects of head-supported mass on head and neck biomechanics, neck muscle fatigue, head tracking performance, target acquisition performance, multitask performance, head ballistic motion, and levels of brain activity.<sup>16</sup> The present study will report only on the biomechanics effort describing head motion as a result of exposure to varying helmet torques and exposure duration. Nevertheless, to more fully understand the experimental environment experienced by the subjects, it is necessary to describe the complete experimental protocol.

Prior to testing, it was necessary to select, screen, and train subjects for participation in the protocol. Subjects were recruited from aviators stationed at Fort Rucker, Alabama. They were solicited by advertising published in the post bulletin, by visits to units on post during training periods, and by word of mouth. The subject pool was then screened to obtain a homogeneous subject set reflective of the average aviator.

Subject selection was first limited to male aviators only. This selection criterion was justified because the current effort was considered a continuation of an earlier one defining short-duration effects of head-supported mass. Had females been included in this protocol, there would have been no baseline from which to compare long-duration exposure effects. Also, at the time the experimental data acquisition phase was performed, there simply were not enough female

aviators on active duty, let alone stationed at Fort Rucker, to support a statistical study. More recently, however, a parallel research effort has been initiated investigating the effects of head-supported mass on female aviator performance.

The next selection criterion was subject stature and weight. Subjects were required to be at the 50th percentile male aviator stature,<sup>17</sup>  $\pm$  10 percent. Subjects were also required to have a weight that was proportional to stature, again, plus or minus 10 percent. Finally, subjects were eliminated from the study if they participated in frequent night vision goggle training (defined as more than one night vision goggle training flight per week), or participated in any physical training exercises that specifically targeted strengthening of the neck muscles. This screening continued until twelve subjects were recruited.

Once the subjects met the selection criteria, they were briefed formally on the nature of their participation in the protocol. This accomplished the requirement to obtain informed consent from the subjects. Of particular importance was ensuring the subjects understood that they would be required to undergo exposure to whole-body vibration while wearing four different weighted helmets. The whole-body vibration exposure would last for four hours, and would be repeated for each of the four helmets to complete the protocol. The complete briefing can be reviewed in appendix A.

Once the subjects were selected and briefed, each was screened by a medical monitor. This was required to ensure the subjects did not have any medical conditions that could be exacerbated by exposure to whole-body vibration or by wearing high-torque helmets. The medical screening form can be reviewed in appendix B. Flight surgeons assigned to the USAARL performed this screening, and later acted as medical monitors for the experimental phase of the protocol. These were required for safety during whole-body vibration exposure in the unlikely event of an accident involving the Multiaxis Ride Simulator (MARS).

Prior to experimental runs, the subjects were familiarized with the experimental setup. Each subject was instrumented with all the apparatus that would be required during the data runs. First, subjects were fitted with a device called a bite bar that held three active infrared position markers. They were required to bite onto a horseshoe-shaped bite plate covered with dental impression material. This obtained an impression of their bite that was used to achieve the same registration of the bite bar for all experimental runs. A fixture holding the infrared markers was then attached to the dental impression. The entire device--the markers and the dental impression--was termed the bite bar.

The bite bar was used to capture the three dimensional position of the head. This was used later to calculate head pitch motion, X motion, and Z motion. Additionally, two infrared markers were attached to a fixture cemented to the skin over the sternum, and two were attached to another fixture cemented to the skin over the first thoracic vertebrae (T1). These captured the motion at the base of the neck: the input motion to the head-neck system. Finally, three markers were attached to the helmet itself, and three markers were attached to the UH-60 seat frame. The helmet markers were used to capture any slippage between the helmet and head by comparing helmet motion to head motion. The last set of three markers on the seat were used to capture seat input motion.

Next, subjects were instrumented with electromyographic (EMG) electrodes placed around the circumference of the neck. Each consisted of an electrode pair arranged to recorded EMG signals in a differential mode. The differential recording allowed for the cancellation of electrical and mechanical noise that was common to each electrode in the pair, and only transduced electrical signals that were dissimilar across the electrode pair. The first set of electrodes was placed over the right and left trapezius muscle at the back of the neck. The next set was placed over the right and left splenius capitus muscle on the sides

of the neck. The last were placed over the right and left sternocleidomastoid muscles at the front of the neck. All electrodes were placed at the level of the fourth cervical vertebrae, or the C4 level, positioned by palpitating for the belly of the muscle, and aligned parallel to the long axis of the muscle. An EMG ground, used to ensure both electrical safety and EMG signal quality, was placed over the bony portion of the lower forearm just above the wrist.

Because of the long-duration of this test, there was a concern that the subjects could become drowsy, or actually fall asleep, during testing. To test for this condition, electroencephalographic (EEG) electrodes were placed on the subject's skull in a four electrode configuration to capture beta brain waves. If these were recorded this would be an indication that the subjects were not alert for the test, and the data for that test would be discarded. Beta waves would be analyzed by USAARL certified EEG technicians.

The subject was then asked to sit in a UH-60 seat placed on top of the MARS. The UH-60 seat, manufactured by Simula, Inc., was stiffened to reduce seat pitch by adding a center front leg. He belted himself into the seat using only the crotch belt and the two lap belts. The shoulder straps were not used because they would interfere with the EMG electrodes around the neck when he voluntarily moved his head.

For the neck muscle fatigue investigation, the subject was required to perform a neck muscle EMG calibration routine. The EMG calibrations would be used to quantify the amount of effort he exerted for each helmet configuration. The procedure for head flexion calibration is described first. This routine began by placing a head band around the subject's head and attaching the head band to a tension load cell. This cell was attached to a fixed metal frame that encircled the his head, and was connected to the head band using a small chain. His upright posture was maintained by adding or removing a number of links in the chain connecting the load cell to the head band. He would then pull in an isometric fashion against the load cell by attempting to

flex the head forward. For the first three pulls he was asked to pull as hard as he could, for up to two seconds, and then release his effort.

The largest of these three trials was considered his maximum voluntary contraction (MVC).

EMG calibration routines were then performed by asking the subject to match his pulling effort to increasing and decreasing target levels. He was shown a computer monitor screen with a graph depicting two bars of a bar chart. One represented the tension on the load cell in the flexion direction. The other represented a target tension that the subject was supposed to match with his flexion effort. The target tension bar would cycle from 0 percent MVC to 30 percent MVC and then return to 0 percent MVC at a rate of 2 percent MVC per second. This cycle took thirty seconds and would repeat three times. This completed the flexion calibration routine. The entire EMG calibration routine was then repeated for head extension efforts. Finally, the complete EMG calibration routine was repeated following the four hour test to capture any changes in neck muscle calibrations.

One final EMG calibration routine was performed prior to testing with vibration. First the subject sat in an upright posture without a helmet for thirty seconds while EMG data were captured. He then donned the experimental helmet loaded with the testing configuration of the day and sat in an upright posture for thirty seconds while EMG data were captured. This was done to assess the level of effort for the unloaded versus the loaded head, absent vibration.

The next step in the familiarization routine was to expose the subject to fifteen minutes of whole-body vibration while they performed all of the testing procedures. For the actual testing, this basic fifteen-minute cycle would repeat sixteen times to make up the total four-hour exposure. For the familiarization trial, the subject wore a helmet with a torque magnitude of approximately the standard aviator helmet, the SPH-4B. The tests performed during the fifteen-minute epoch will be described next.

The first test of the fifteen-minute epoch was the biomechanics test. Here the subject was asked to sit in a relaxed upright posture and face towards a target located at eye level at a distance of eighty inches toward their front. This lasted one minute. About fifteen seconds into the test, a fifteen-second data acquisition window was activated capturing both EMG and position data. The instrumentation for the position measurements of the biomechanics test will be fully described in the instrumentation section later in this chapter.

The second test of the fifteen-minute epoch was a two minute head tracking task. For this test the subject was required to point a helmet mounted columnated beam (a light spot) at a moving target eighty inches to the front. The target would move in a random walk motion at a rate of four degrees per second. The range of the target was plus or minus thirty five degrees in azimuth, and plus or minus fifteen degrees in elevation. The subject was required to keep the spot at the center of the target during the target motion. Errors were measured for X and Y deviations from the center of the target at a sampling rate of 20 Hz.

The third test of the fifteen-minute epoch was a five minute vigilance task used to assess target acquisition reaction times. Here subject was asked to monitor four red-light-emitting diodes (LEDs) located in a rectangular arrangement at the periphery of their visual perception. The LEDs would flash on in a random pattern and the subject was required to turn them off as fast as he could. A LED was turned off by having the subject point the head-mounted columnated beam at a photosensitive diode collocated with it. The time between the LED flash and his "hitting" it was measured. Neck muscle EMG was also measured between LED-flash to LED-hit to capture the EMG effects of ballistic head motion.

The final task of the fifteen-minute epoch was the seven minute Synthetic Work Environment (SWE) task. This is thought to test a multitasking skill required in aviation. Because of the difficulty of this task, each subject was given ten training sessions of twenty

minutes each over at least five days. Performance scores were posted to encourage maximum efforts through competition.

For the SWE tests, the subject was required to perform four computer generated tasks simultaneously (appendix A). The first was a seven letter recognition task. Once having seen the target seven letters, he would have to tell if a presented letter was or was not in the target list. If the response was correct he would earn points. If the response was wrong, he would be assessed penalty points.

The second task involved auditory recognition. The subject was presented with one of two tones. If the tone was the high tone, he was to respond. If the tone was the low tone, he was to ignore it. He received points for correct responses and was penalized points for incorrect responses.

The third task was a three column addition task. The subject was required to add two numbers of three digits each. If he got the correct answer he would receive points. Penalty points were assessed for incorrect answers.

The fourth task involved position discrimination. Here the subject was required to let a moving bar drift towards one end of a predetermined and known interval. The closer he let the target bar get to the end before resetting the bar, the more points he would receive. If he let the bar touch the end, penalty points would be assessed.

All the SWE tasks were performed simultaneously on a large computer projection screen centered at eye level and to the front of the subject. This was partitioned into four quarters with one task running in each section. The subject was required to move a track ball to the correct positions and press track ball buttons to register responses. Incorrect responses would be noted with a computer beep and the subtask would be reset. Correct responses would also reset the subtask but with no audible beep.

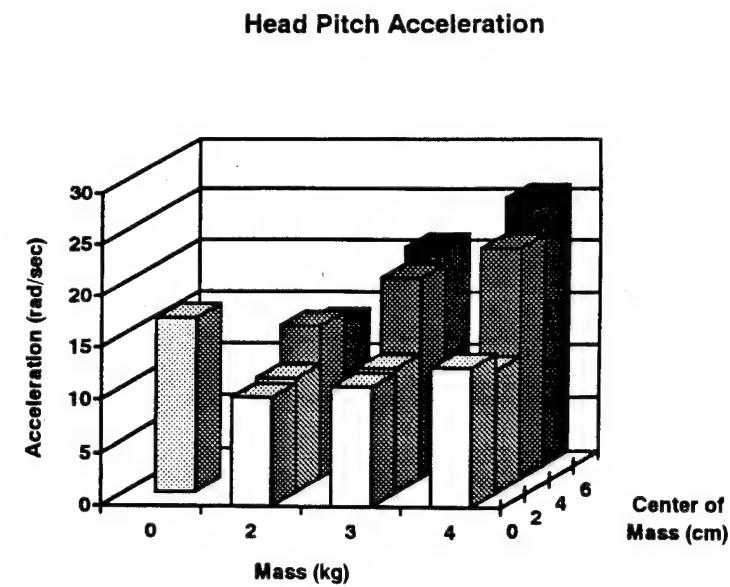

Following the familiarization trial, the subject was given at least a 48-hour break before a data trail was initiated. For the actual

testing, the tests described for the basic fifteen-minute epoch were repeated sixteen times for a total of four hours of testing. A break was given at the two-hour point of the four-hour test. This lasted between five and seven minutes. The subject was allowed to dismount the testing apparatus, remove the helmet, visit the restroom, drink water, and rest in the remaining time. They remounted the MARS and were connected to the instrumentation. Testing was reinitiated for the remaining two hours. A break of at least 48 hours between data trials was scheduled to ensure recovery from fatigue.

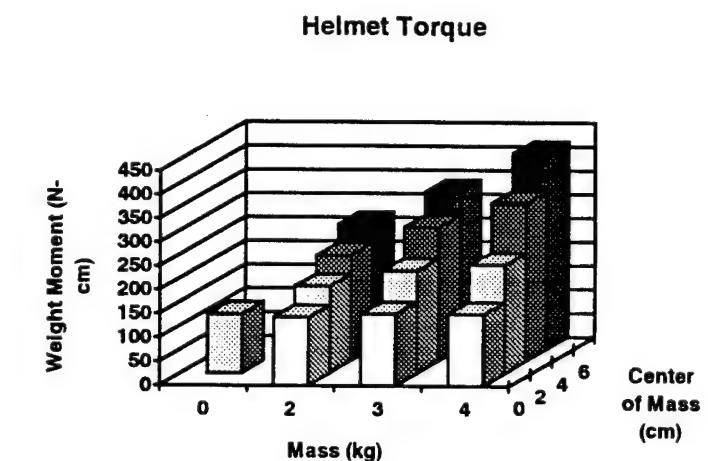

#### Helmet Loads

In determining the current recommended practice for helmet loading for U.S. Army aviation, the USAARL used short duration exposure not exceeding twenty minutes, and using twelve helmets. The USAARL determined that 90 N·cm was the limit for head-supported loads measured relative to the AO complex as determined from head pitch responses. That is, the head pitch response was greater for helmets with a torques larger than 90 N·cm as compared to lower torque helmets. The lower torque helmets were not different from the no-helmet case. Figure 4 shows these results with the higher helmet torques showing a greater head pitch response over both the lower torque helmets and the unloaded head.

For the current investigation, it was impractical to test each of the original twelve configurations for long-duration exposure. This would have required at least of 567 hours of testing, or more than one-half of a year of experimentation. Subject availability would have been severely limited for such an effort. Therefore, helmet configurations chosen for the current study were selected to cut diagonally across the helmet configurations shown in figure 5 with the highest load of 4 kg and a center of mass at +6 cm relative to the AO complex, to a helmet configuration of 0.5 kg with a center of mass at the AO complex.

**Figure 4.** Short-duration head pitch response. Head pitch response for short-duration whole-body vibration exposure.

**Figure 5.** Short-duration helmet torque. Helmet torque for short-duration whole-body vibration exposure. Helmet torques represent system totals including the 122.9 N·cm of the head.

The four helmet configurations are shown in figure 6. These also represented helmet loads seen in the Army aviation environment: the standard SPH-4b aviator helmet, a SPH-4b helmet with the sun visor down, a SPH-4b with the ANVIS night vision goggle (NVG), and a SPH-4 with and ANVIS NVG and a M-43 chemical mask. The static weight moment of these helmets is given in table 1.

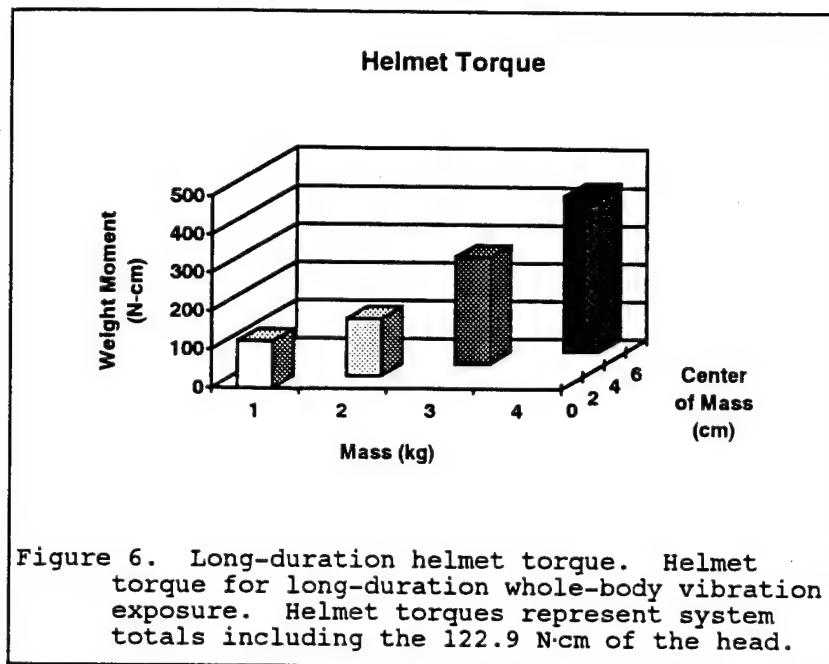

Table 1. Helmet description with weight moments

Helmet Description	Measured Weight Moment (Helmet Alone) (N·cm)	Estimated Weight Moment (System) (N·cm)	Experimental Weight Moment (System) (N·cm)
SPH-4b	-19.5	103.4	122.9
SPH-4b with visor down	19.7	142.6	149.8
SPH-4b with NVG	144.6	267.5	280.2
SPH-4b with NVG and M-43 Mask	297.8	420.7	410.8

### Subject Grouping and Helmet Rotation

When subjects were selected for participation in this study, they were placed in four groups. Group 1 was filled with the first four. Similarly, the other groups were filled sequentially as subjects entered the protocol.

Helmet presentation was performed using a rotational paradigm. This was used rather than a random presentation to allow for the testing of presentation effects. For example, group 1 was presented with helmets 1, 2, 3, and then 4. For subsequent groups, the helmet presentation was rotated by one helmet with Group 2 being presented with helmets 2, 3, 4, and then 1. Table 2 shows the complete rotation for each group.

Table 2. Helmet configuration and subject grouping

Group	Subjects	Helmet
1	1, 2, 3	1, 2, 3, 4
2	4, 5, 6	2, 3, 4, 1
3	7, 8, 9	3, 4, 1, 2
4	10, 11, 12	4, 1, 2, 3

### Instrumentation

#### Position Measurement system

The instrumentation discussed in this section applies only to the position measurement system. This limitation was imposed because the position data were the only ones analyzed in this thesis. The reader is referred to the USAARL for instrumentation and data analysis information pertaining to the other portions of the complete experiment.

Positional recordings were performed using a Northern Digital Optotrack model 310 position measurement system. This uses three cameras that are triangulated to measure three dimensional positions of pulsed infrared diode markers. The resolution of the Optotrack system

varies in relation to the recording distance between the cameras and the markers. For the current effort, resolutions were calculated to be less than 0.01 millimeters.

Thirteen active pulsed infrared markers were placed in the view of the three camera Optotak system. Three markers were placed on the bite bar, three on the seat, three on the helmet, two on the sternum fixture, and two markers on the T1 fixture. Marker locations for the bite bar are shown in figure 7. Marker data were acquired at a rate of 200 frames per second, with each frame comprising the thirteen markers. Raw sensor position data were stored on computer hard disk and later converted to actual positional measurements following testing.

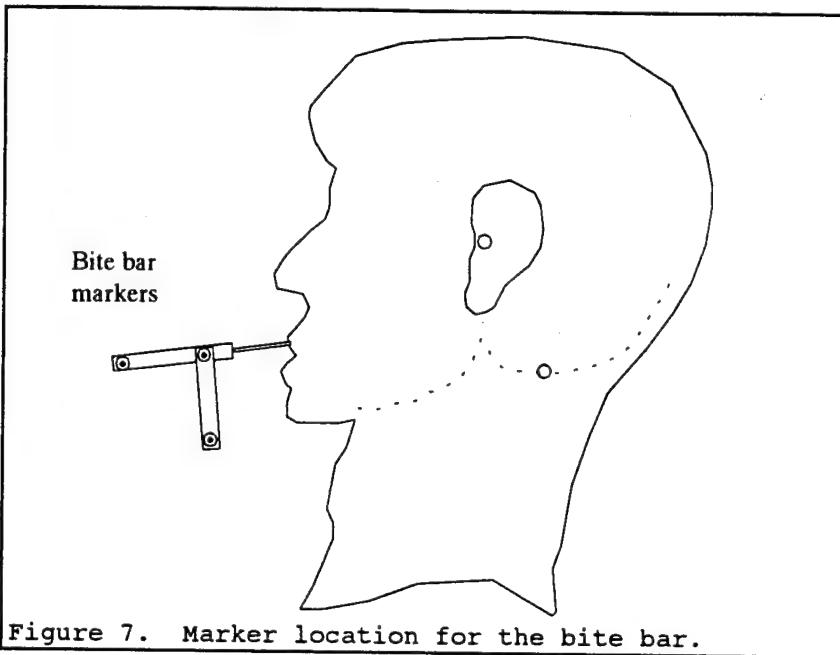

Figure 7. Marker location for the bite bar.

#### Multiaxis Ride Simulator (MARS)

The MARS is a three-axis (X, Y, Z) whole-body vibration platform capable of simulating helicopter motion. It can reproduce vibration frequencies ranging from 1 Hz to 35 Hz,  $\pm 3$  dB, with peak vibration spikes up to five times the force of gravity. Vibration data

from a UH-60 helicopter were acquired by placing a triaxial accelerometer on the seat frame and recording accelerations while flying at a straight and level attitude at normal cruise speeds. These were then sampled by the MARS and reproduced to recreate the UH-60 vibration on the seat rail supporting the test UH-60 seat bolted to the top of the MARS. A complete description of the MARS can be found at appendix c.

#### Data Analysis

Only the position data of the biomechanics test will be analyzed in this thesis. Because of the multidisciplinary nature of this effort, the USAARL has distributed other data sets to qualified investigators for analysis. For example, the EMG data have been offered to muscle physiologists, and cognitive performance data have been offered to the research psychologists. The USAARL will consolidate the results from the various disciplines and develop a comprehensive report. The discussion of the data analysis procedures will be limited to the position measurements of the head, the head motions, and the statistical analysis of these data.

#### Equations of Motion

Position data from the bite bar were collected for each of the 16 epochs covering the four hour test. The raw Optotrak sensor data were converted to three dimensional position data following testing. These were processed to create head motion data for the midsagittal plane covering head pitch, X, and Z displacements. These investigations were limited to planar motion because the head has been shown to move only in a planar fashion due to axial vibration.<sup>18,19</sup> UH-60 vibration data are primarily axial with only 10 percent of the signal found in the other primary directions.

The purpose of the equations of motion for the head (derived below) was to translate the sampled bite bar data to the motions of the head at the AO complex. This was chosen as the point of interest for head motion because it is the location of the pivot point of the head on

top of the spine. The muscles in the neck supporting the head act through this point. The equations of motion were derived from the geometry of the head relative to the AO complex and the bite bar markers. Figure 7 shows the bite bar markers and the AO complex superimposed on a fictional profile of a subject's head and neck. Lateral photographs of the subjects were taken to capture the position of the bite bar relative to anatomical landmarks. The points  $(X_1, Z_1)$  and  $(X_2, Z_2)$  represent the front most marker and the descendent marker on the bite bar, respectively (figure 8). Given three dimensional positional measurements of  $(X_1, Z_1)$  and  $(X_2, Z_2)$ , the Z-axis, X-axis, and pitch motion at the AO complex, or at the point  $(X_3, Z_3)$ , can be determined as follows.

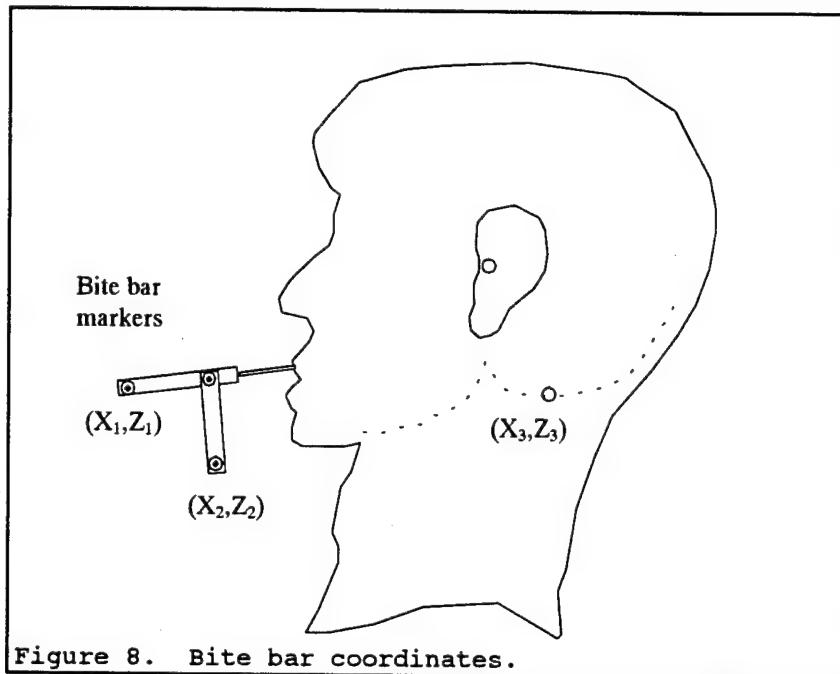

Figure 8. Bite bar coordinates.

First, AOC pitch motion,  $\theta_1$ , can be found using positional measurements directly from the bite bar, yielding

$$(1) \quad \theta_1 = \arctan\left(\frac{Z_1 - Z_2}{X_2 - X_1}\right)$$

Next, the X displacement of the AOC can be found using

$$X_3 = X_1 + (d_1 + d_3 + d_4) \cos \theta_1 + (d_2 - d_5 + d_6) \sin \theta_1$$

and Z displacement of the AOC can be found using

$$Z_3 = Z_1 + (d_2 - d_5 + d_6) \cos \theta_1 - (d_1 + d_3 + d_4) \sin \theta_1$$

where  $d_1$  is measured inferior from the bite bar to a perpendicular from the external auditory meatus (EAM), and  $d_2$  is the length of the perpendicular to the EAM (see figure 9). The variables  $d_3$  through  $d_6$  can

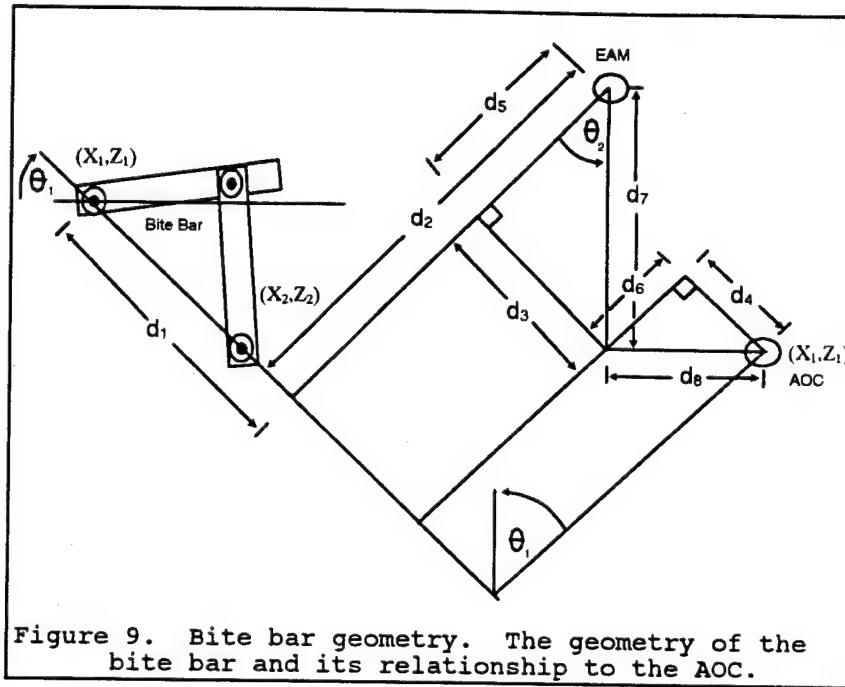

Figure 9. Bite bar geometry. The geometry of the bite bar and its relationship to the AOC.

be redefined as

$$d_3 = d_7 \sin \theta_2$$

$$d_4 = d_8 \cos \theta_2$$

$$d_5 = d_7 \cos \theta_2$$

$$d_6 = d_8 \sin \theta_2$$

where  $d_7 = 22$  mm and  $d_8 = 10$  mm from physical measurements,<sup>20</sup> and where  $\theta_2$  is measured from lateral photographs capturing the subject's profile. The fully expanded equations become

$$(2) \quad X_3 = X_1 + (d_1 + 22 \sin \theta_2 + 10 \cos \theta_2) \cos \theta_1 + (d_2 - 22 \cos \theta_2 + 10 \sin \theta_2) \sin \theta_1$$

and

$$(3) \quad Z_3 = Z_1 + (d_2 - 22 \cos \theta_2 + 10 \sin \theta_2) \cos \theta_1 - (d_1 + 22 \sin \theta_2 + 10 \cos \theta_2) \sin \theta_1 \quad (3)$$

#### Signal Processing of Head Motion

The equations of motion (1, 2, and 3 above) were then used to translate positional data into head motion data at the AO complex. The head motion data of this experiment characteristically are vibration data. This type of information is routinely analyzed in the frequency domain using a Fourier analysis technique. The emphasis in Fourier analysis is to detect peak resonant responses and resonant frequencies.

Care must be exercised in applying the Fourier techniques, especially the discrete Fourier Transform (DFT), to avoid inadvertently contaminating the results. Head motion data were therefore processed to capture peak resonant responses using standard signal processing techniques.

The signal processing techniques used in analyzing head motion data began with extracting a 256 point segment from the 1500 point data sequence generated for each head motion at each of the 16 epochs. This small sequence was first filtered to remove any average (DC) value. Removing the DC value eliminated any large constant signal that would have contaminated low frequency responses. Because head pitch resonance is at a low frequency of 4.5 Hz, this step was necessary to ensure good fidelity.

The extracted signal was then multiplied by a Hamming window.<sup>21</sup> This process, known as windowing, is used to remove any discontinuities at the ends of the signal. This step is required due to an assumption in DFT analysis that the extracted signal is representative of the larger complete signal. In fact, the mathematics of the DFT require that the extracted signal can be concatenated to itself to create a longer sequence. In this concatenation procedure there can be no

discontinuities when the end of one signal section is attached to the beginning of the repeated signal section. If discontinuities are not removed the resultant DFT will be contaminated with high frequency signals posing as low frequency data.

Another assumption for applying the DFT is that the analyzed signal must meet the condition of wide sense stationarity. This means that the signal does not have a changing mean or standard deviation. It would appear that a rejection of the null hypothesis ( $H_0$ : that there would be no change in head motion over time) would be a violation of this criterion. However, if the time segment for which the analysis is performed is short enough, then wide sense stationarity can be assumed to have been satisfied.

The windowed data were then processed using a high speed DFT routine<sup>22</sup> originally written in FORTRAN and translated into C for this thesis. Subsequent 256 point data segments were similarly processed using an overlap and add method.<sup>23</sup> This technique further increased the fidelity of the DFT results. Finally, resonant peaks were identified and extracted for later statistical analysis. A complete flow of signal processing techniques is shown in figure 10.

#### Statistical Analysis

Head motion data analysis will begin by viewing frequency domain plots. These will be used to verify the quality of the data. Expected results include the identification of four peaks of decreasing size ranging from 4.25 Hz to 17 Hz. The first peak at 4.25 Hz is expected to be the largest peak, representing the resonant head motion response generated from the one blade passing frequency of the UH-60 main rotor blade system. The one blade passing frequency is the frequency at which one main rotor blade completes one revolution. The next peak is expected at around 8.5 Hz representing the two blade passing frequency of the UH-60 and the first resonance of head motion. The third peak should occur around 12.75 Hz representing the second

resonant peak of head motion. The last peak is expected at around 17 Hz represents the four blade passing frequency of the UH-60, as well as the fourth resonance of head motion and the second resonance of the two blade passing frequency.

10. Locate frequency at peak response
11. Perform statistical analysis

Figure 10. Signal analysis flow chart.

Peak primary resonant head motion data will be found for head pitch, X and Z motion using a local maximum search routine centered at 4.5 Hz. Data will be arranged to perform two way analysis of variance using helmet and epoch as the independent variables. Where significant differences are found, a Tukey multiple comparison of means test will be performed within independent variables to identify differences.

#### Assumptions

The following assumptions are made in support of this study.

- (1) The volunteer aviators for this study are a representative sample of the Army aviator population.

(2) The MARS whole-body vibration simulator creates the same biomechanical stress in the aviators as actual UH-60 helicopter flights.

(3) Applying myoelectric sensors and position sensors to the volunteer aviators does not alter their biomechanical response as compared to the noninstrumentation situation found in actual UH-60 helicopter flight.

(4) The motion of the head on the neck due to UH-60 whole-body vibration exposure is in the angular range and rate requiring only static voluntary muscular contraction to support the head.

(5) Subject posture does not change throughout the four hour test.

(6) The motion of the head and neck resulting from UH-60 whole-body vibration is limited to the midsagittal plane with pitch motion dominant over X and Z-axis motion.

(7) Aviators spend 80 percent or more of their time in the crew station in an upright posture, reflecting the appropriateness of the upright posture selected for the experimental trials.

## CHAPTER 4

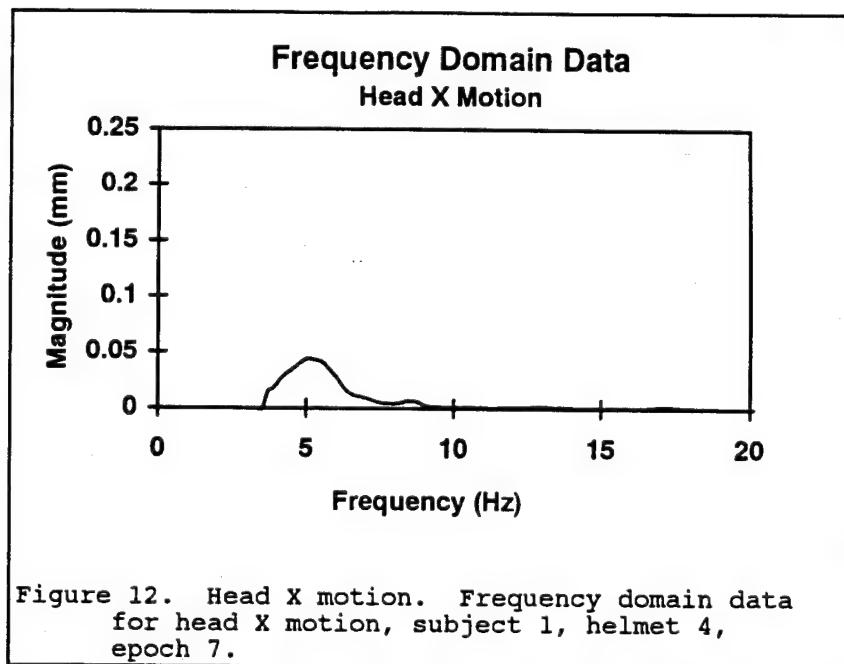

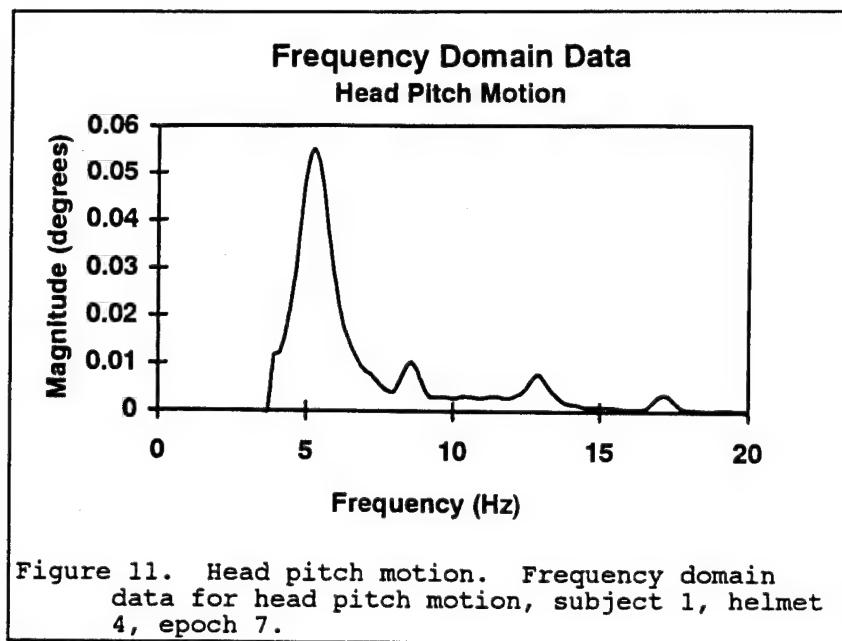

### ANALYSIS

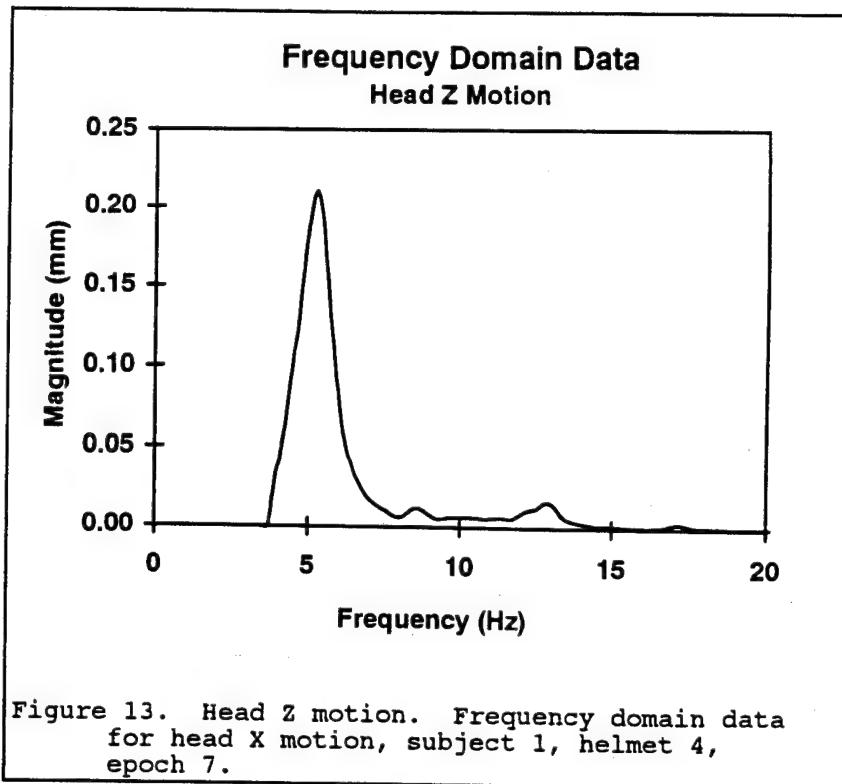

The head motion data acquired in this study were generated from a vibrating platform simulating whole-body vibration experienced by UH-60 helicopter pilots. Because vibration data are best described in terms of their magnitude and frequency, the calculated time domain head motion data were processed to generate frequency domain data. The initial frequency domain analysis was performed to assess the quality of the frequency domain data resulting from the application of the signal processing routines.

An example of the frequency domain data is shown at figure 11. The plot was generated from one subject, one helmet, using the first epoch of the 16 epoch test. It shows the dominant head pitch resonance at 5.1 Hz with a magnitude of 0.055 degrees. Other peaks occurred at frequencies of 8.6 Hz, 12.9 Hz, and 17.2 Hz. These upper three peaks correspond to the resonant characteristics of the UH-60 main rotor blade frequencies. For example, the one blade passing frequency of the UH-60 is at 4.3 Hz. Harmonics of this frequency are at 8.6 Hz for the two blade passing frequency, 12.9 Hz for the three blade passing frequency, and 17.2 Hz for the four blade passing frequency.

Examples of X and Z motion are shown in figures 12 and 13. Both plots show the head resonance at 5.1 Hz. The other three expected peaks at 8.6 Hz, 12.9 Hz, and 17.2 Hz are evident to varying degrees in the plots. The X motion data of figure 12 show a small peak at 8.6 Hz, with the other peaks evident only when viewing the supporting data. Z motion data of figure 13 show the 8.6 Hz peak along with the 12.9 Hz peak. The peak at 17.2 Hz is only evident from the supporting data. By yielding expected magnitudes and frequencies for head pitch, figures 11,

12 and 13 serve to confirm the functioning of the Fourier analysis routines, and confirm the calculations of head pitch motion.

The purpose of generating the frequency domain data was to capture the peak head pitch, X, and Z motion data occurring at resonance during each time period. Head motion data were processed as described above to generate frequency domain data for each of the 16 epochs covering the four hour data runs. An example of the head pitch motion for each of the 16 epochs is shown in figure 14 for one subject and one helmet. The resonant peaks at 5.2 Hz range from 0.029 degrees to 0.575 degrees, a range over four times that of the other peaks.

The variability in the resonant peak shown in figure 14 was investigated to assess the effect of helmet type or exposure duration on peak amplitude. This analysis was performed for each head motion. A local maximum was found using a peak picking algorithm to capture the peak data ranging from 3 Hz to 8 Hz. Figures 15-18 show, for each helmet, peak head pitch data for each of the 12 subjects plotted by epoch. X and Z head motion examples are similar, but for brevity are not shown.

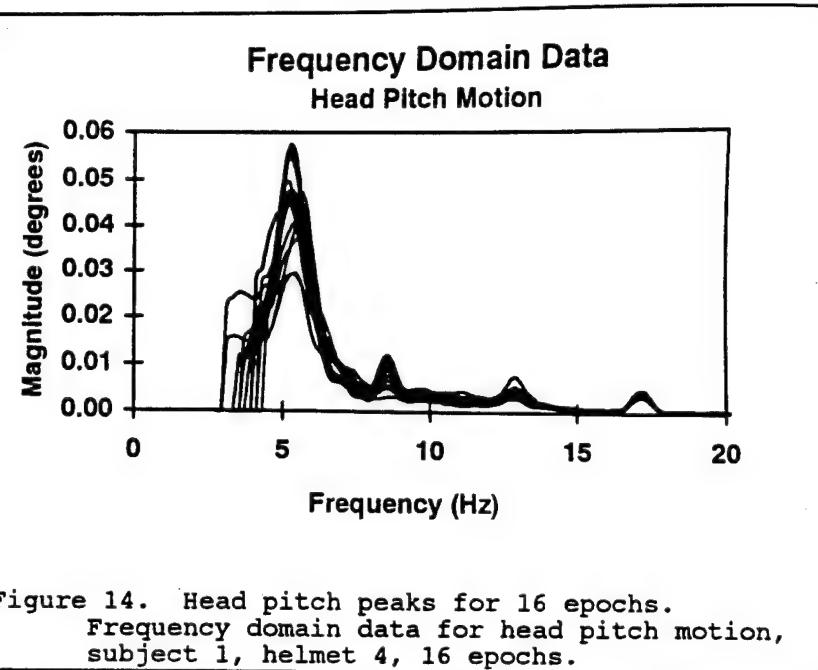

Figure 14. Head pitch peaks for 16 epochs.  
 Frequency domain data for head pitch motion,  
 subject 1, helmet 4, 16 epochs.

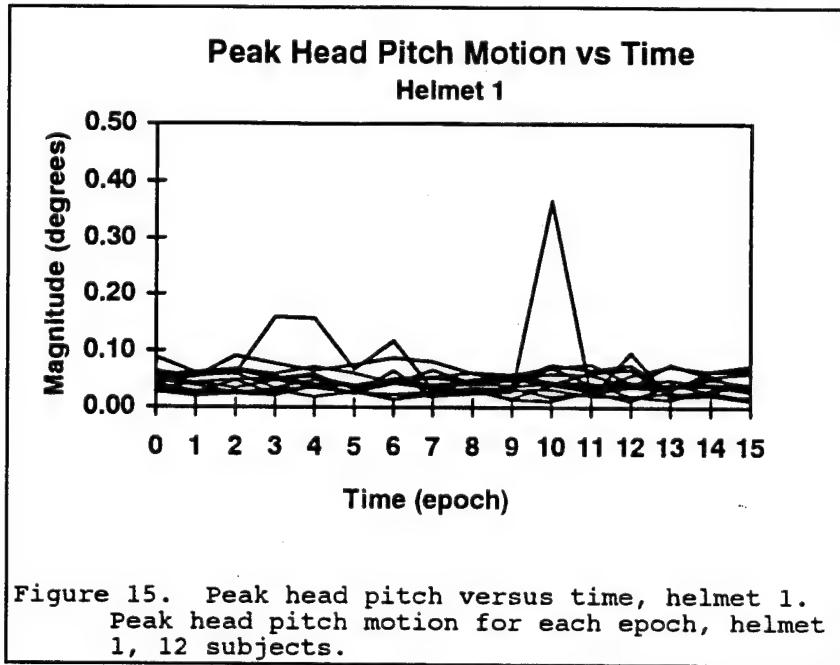

Figure 15. Peak head pitch versus time, helmet 1.  
 Peak head pitch motion for each epoch, helmet  
 1, 12 subjects.

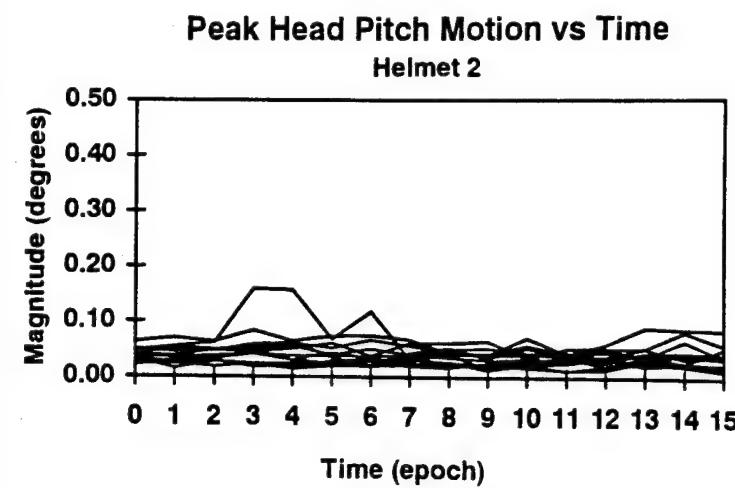

Figure 16. Peak head pitch versus time, helmet 2.  
Peak head pitch motion for each epoch, helmet 2, 12 subjects.

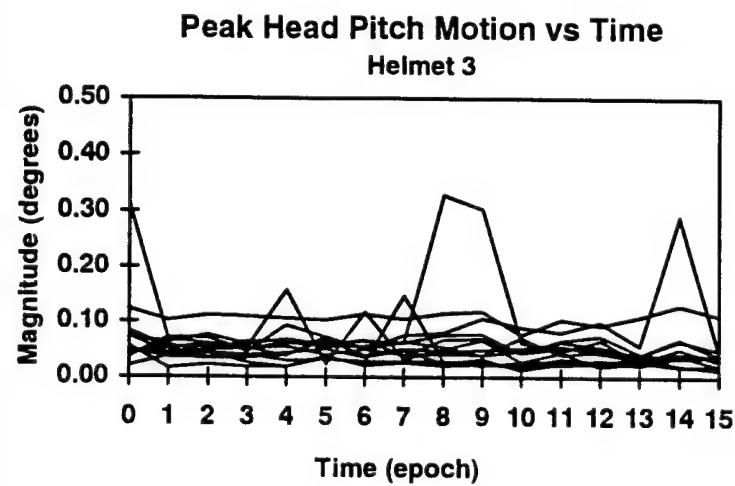

Figure 17. Peak head pitch versus time, helmet 3.  
Peak head pitch motion for each epoch, helmet 3, 12 subjects.

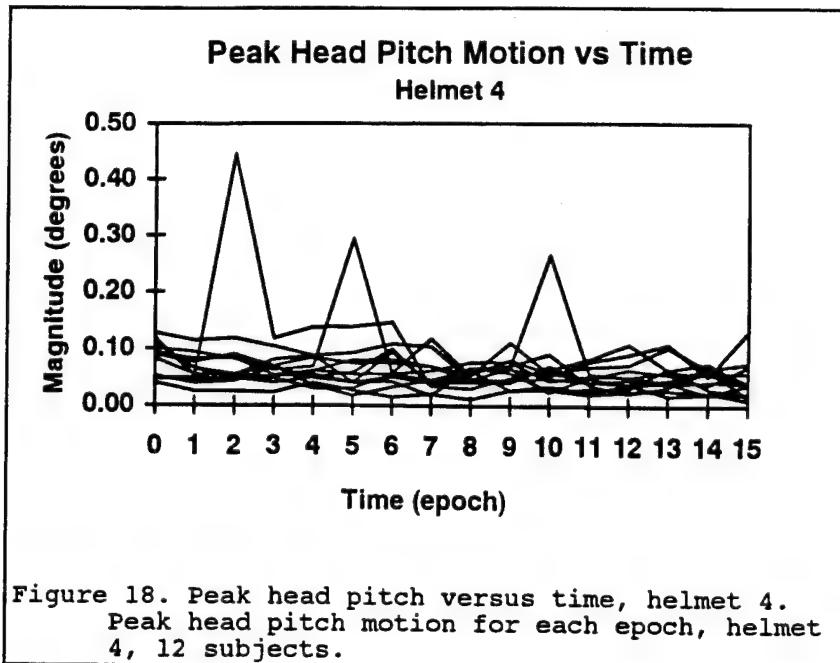

Figure 18. Peak head pitch versus time, helmet 4.  
Peak head pitch motion for each epoch, helmet 4, 12 subjects.

The peak response versus epoch data of figures 15-18 show relatively flat responses for head pitch over time with occasional outliers. There appears to be no apparent pattern regarding the outlier data relative to timing, subject, or helmet. These data were then averaged for all subjects and plotted in figures 19-21. These averaged plots show head motion for each of the four helmets plotted by epoch.

The pitch data of figure 20 are relatively flat, and may even be decreasing over time for each helmet. This figure also shows an increasing pitch magnitude for helmets 2 through 4, that is, for helmets of increasing torque loads. This trend appears only in the first half of the test period. In the second half, the separation in the pitch response among the three highest torque helmets appears to taper off over time. The lowest torque load, helmet 1, does not follow this hierarchical trend in the first half of the testing, remaining with a pitch response that is larger than the next higher torque helmet. Near the end of the testing the lowest torque helmet has the least pitch magnitude response.

### Average Peak Head Pitch Motion vs Time

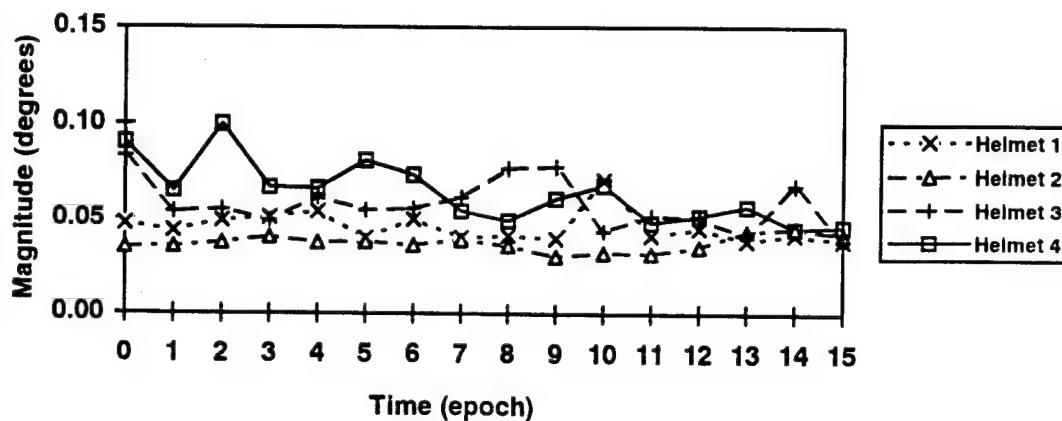

Figure 19. Average peak head pitch motion versus time. Peak head pitch motion for each epoch, helmet 4, 12 subjects.

### Average Peak Head X Motion vs Time

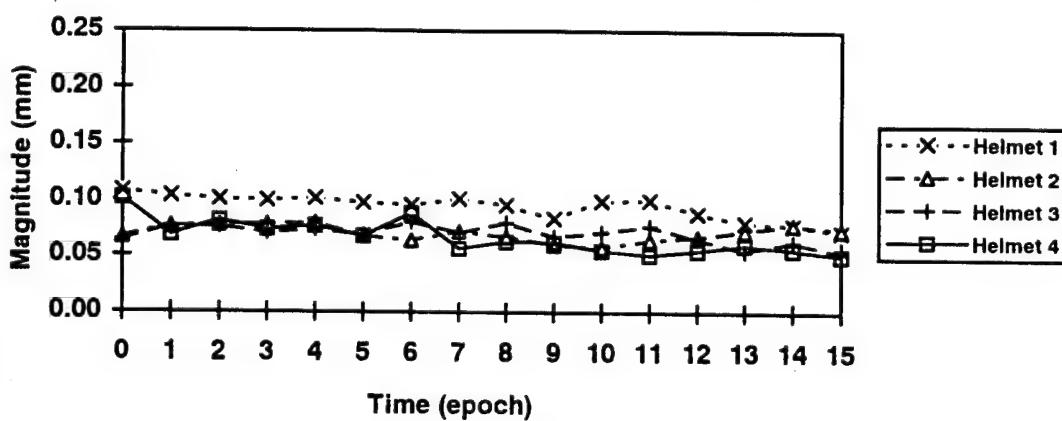

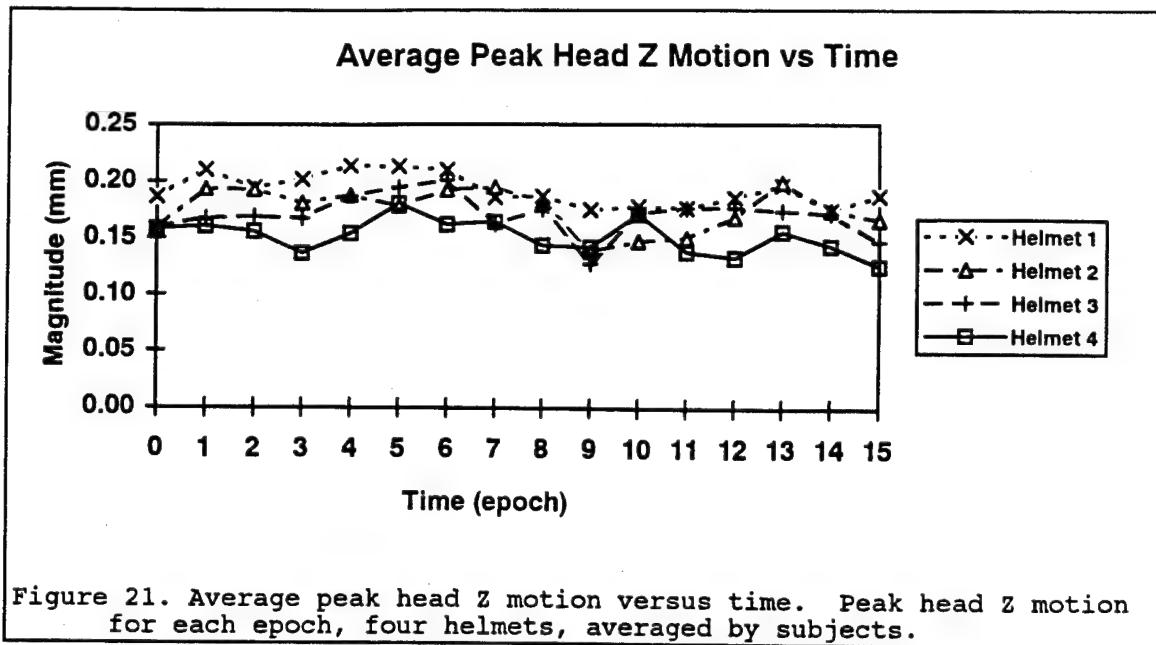

Figure 20. Average peak head X motion versus time. Peak head X motion for each epoch, four helmets, averaged by subjects.

Head X motion and Z motion of figures 20 and 21 appear similarly flat over time. The only trend that is remotely apparent is for an increased magnitude response for X and Z motion with the lowest torque helmet, helmet 1, as compared to the heavier torque helmet, helmet 4. Average X motion response also remained approximately 50 percent of the Z motion response.

#### Statistical Analysis

Statistical analysis was performed to assess the significance of the trends shown in the above plots. A two way analysis of variance (ANOVA) was performed using independent variables of epoch and helmet. The purpose of this was to assess the effects of either time, or helmet torque, or the interaction between these two variables, as having an effect on the peak head motion. Results indicated significant differences ( $P<0.05$ ) for helmet torque, but no significant differences for epoch, and no significant interaction effects. These results require that the first null hypothesis for exposure duration not be rejected. That is, the hypothesis that head motion will not change as a result of exposure duration is not rejected. However, the second null

hypothesis—that head motion will not change as a result of helmet torque—is rejected. Written in the alternative format, and for the conditions of this test, helmet torque does have an effect on head motion, but exposure duration does not.

Even though ANOVA results indicated no significant differences for epoch, or exposure duration, a multiple comparison of means test was performed for helmet type at each epoch. A variety of tests that are designed to protect the user from violating basic statistical assumptions are available to perform multiple comparisons of data sets. For example, when using contrasts with ANOVA, it is assumed that one sample group will be used in a comparison only one time. If it is compared more than once, a correction—called a Bonferroni correction—must be applied. This correction divides the level of significance by the number of comparisons being made. The Tukey test is a procedure with a built-in correction factor.

The Tukey test was used to produce the results of table 3. The data of table 3 indicate that differences exist among helmets in the early epochs but not in the later epochs. Consistent differences were found between helmet two and four, that is, the highest torque helmet was different from the next to lowest torque helmet. Only one epoch

Table 3. Tukey test for helmet at each epoch.

Motion	Epoch	Differences ( $p < 0.05$ )
Pitch	0	$2 \neq 3, 4$
	1	$2 \neq 4$
	2	$2 \neq 4$
	6	$2 \neq 4$
X	0	$1 \neq 4$
Z	3	$1, 2 \neq 4$

resulted in differences for X or Z motion. Here consistent differences were found between helmets one and four—the highest and lowest torque helmets.

The ANOVA results were used to justify averaging across epoch and performing a multiple comparison of means for helmet type. The Tukey test was performed for helmet torque, resulting in significant differences as shown in table 4. These data indicate that the highest torque helmet is significantly different from the two lowest torque helmets, and the next to highest torque helmet is significantly different from the lowest torque helmet, for all head motions. Figures 22-24 show the averaged head motion data (for epoch and subject) for each of the four helmets by head motion.

Table 4. Tukey test for helmet.

Motion	Differences ( $p < 0.05$ )
Pitch	$1, 2 \neq 3, 4$ $3 \neq 4$
X	$1 \neq 2, 3, 4$ $2 \neq 3, 4$
Z	$1 \neq 3, 4$ $2, 3 \neq 4$

## CHAPTER 5

### DISCUSSION, CONCLUSIONS, AND RECOMMENDATIONS

#### Discussion

The two primary results of this study are (1) that head motions were affected by helmet torque, and (2) that head motions did not change with exposure duration. The first result confirmed the findings of earlier studies showing that head pitch response increased when helmet torque increased. The second result was unexpected. It was expected that head pitch response would increase over time with the onset of muscle fatigue. This fatigue would cause a reduction in the spring constant of the muscle and a resultant shift in head pitch resonant response to lower frequencies. This shift would pass the head pitch response through the UH-60 one-blade-passing resonant frequency, which is close to, and lower than, the head pitch resonant frequency. When the head pitch resonance frequency hit the UH-60 resonance frequency there would be an increase in the input vibration with a resulting increase in head pitch response. That there was no increase in head pitch response suggests that this mechanism was not active under the conditions of this study. The details supporting this conclusion will be discussed along with the signal processing details behind the data analysis.

One error commonly made in signal processing is that researchers string together analysis routines without knowing the effects of each of the steps on the quality of the results. Simply stringing routines together without knowing, and testing for, the relative effects of each stage of the algorithm can lead to erroneous results. For example, decisions must be made as to the time domain window length, the window shape, the sampling frequency, the amount of

overlap used, the effects of filtering, and other factors that affect the overall quality of the frequency domain results. The algorithm used for this study was developed to yield low frequency data that could be used to distinguish between spikes that were separated by less than one or two hertz.

The frequency response plots of figures 11-14 are examples of the results of the signal processing routines outlined in figure 10. The original data contained large low frequency spikes that were filtered out using a high pass frequency domain filter. These were most likely due to small fluctuations in posture arising from breathing, beating of the heart, and other autonomic postural changes. Although such phenomenon may be of interest to other investigators, they have little effect on head pitch dynamics and are not of interest to the current study. The spikes were located at a frequency below the 5 Hz head pitch response and were separated from the head pitch resonance by a distinct minimum in the data. This minimum, typically located around 3 Hz to 4 Hz, was used as the cutoff frequency for the high pass filter.

Even though these low frequency spikes were large—as much as ten times the size of the head pitch resonant spike—the signal processing routines were designed to be robust enough to separate them from the resonant head pitch spikes. The difficulty here is that often times a large spike can spread over into adjacent frequencies and cover up data spikes that are close to the center frequency of the adjacent spike. Occasionally another small spike was detected at around 4.3 Hz, that looks like a low frequency shoulder on the head pitch resonant spike. This shoulder was actually due to the one-blade-passing-frequency of the UH-60, and is the primary resonant peak of this helicopter. The other small spikes in the frequency domain plots, those beyond the head pitch resonant peak, are harmonics of this 4.5 Hz spike.

The UH-60 resonant peak is of interest in its relationship to the head pitch resonant peak and the effects of muscle fatigue. One possible result of muscle fatigue could be a reduction in head pitch

resonant frequency through the UH-60 resonant peak. A possible explanation for this shift could be a reduction in muscular tension in the neck. This could decrease through a reduction in the number of muscle fibers firing in the active motor units, by an overall reduction in the firing motor unit pool, by recruiting new motor units that have less of a capacity to produce tension, or by any combination of these mechanisms. A reduction in tension would be represented in biomechanical modeling by a reduction in the spring constants of a mass-spring system where the spring represents the muscle. This would result in a reduction in the resonant frequency of the system. For example, hang a mass off of a spring and it will bounce up and down at a particular frequency. If the spring is replaced with a weaker spring, the mass will bounce up and down at a slower frequency.

A gradual reduction in the head pitch resonance would have moved the resonant frequency through the 4.3 Hz UH-60 resonant frequency. At this frequency there would have been an increase in the amount of energy exciting the head-neck system. Under these conditions head pitch should increase. However, in this study, head pitch was shown to remain flat over time, or may even have shown a decreasing trend. One possible explanation for this is that muscle fatigue did not occur, at least to the extent that there was a reduction in muscle tension. Another explanation is that fatigue did occur, but the inherent mechanisms of maintaining muscle tension were enough to maintain head pitch control. The head pitch data analyzed in this thesis were not sensitive enough to indicate muscle fatigue. The data captured in the other phases of the overall experiment, however, may be useful in assessing the degree of muscle fatigue.

Head pitch still could be used to assess changes in resonant responses, and could indicate changes in muscle function. For example, if a random vibration replaced the UH-60 vibration for a brief period in the biomechanics test, head pitch resonant frequency could be tracked more accurately over the period of the entire test. Or a transfer

function, showing the degree of output response resulting from the input function, could be used with the existing data to assess changes in resonant characteristics. These tests could be performed with the existing data and may offer other interesting insights into the nature of the head pitch response.

The plots of figures 15-18, showing head pitch response for each helmet and for all subjects over time, contain occasional large spikes in the data sets. These should not be interpreted as significant data trends as there appears to be no regularity or pattern to their occurrence. For example, no trends are apparent relative to the epoch, subject, or helmet. These spikes should probably be interpreted as outliers in the data sets. Nevertheless, they did have an effect on the statistical analysis for at least one test, showing an increase in variance where they occurred among the epochs. This caused the rejection of a statistical result for Z head motion over time for a test requiring uniformity of variance. However, for the most part, these outliers were not factors in the overall statistical analysis.

The averaged plots of figures 19-21 reinforce the nearly flat head motion response seen in the earlier plots for pitch, X and Z motion across epochs. However, differences do exist in the relative response for head pitch among helmets in the first half of the experiment that do not appear in the second half. For head pitch motion, significant differences were found among the helmets in the first three epochs, and in the sixth epoch. Only the third epoch showed significant differences for Z motion, and only the zeroeth epoch showed differences for X motion.

The plot of figure 19 shows a trend for decreasing pitch response with decreasing helmet torque. This trend fits for helmets 4, 3 and 2, but not for helmet 1. Helmet 1 shows an increase in head pitch response over that of the next two higher torque helmets. The data of table 1 offers an explanation. Helmet 1 was configured with a torque that actually decreased the net torque about the AO complex. The torque

for the head alone has been measured at 122.9 N·cm. Helmet 1 had a center of mass that was behind the AO complex and caused a reduction of the total system torque (the combined head and helmet torque). The system torque was estimated at 103.4 N·cm, or 19.5 N·cm less than the head alone. The net effect of this reduction in torque is thought to have caused an instability in the head-neck system resulting in an increase in head pitch response.

Two way ANOVA for helmet type and epoch showed significant differences for helmet type, but no differences for exposure duration. This latter result was unexpected. The expected result was an increase in head pitch motion coincident with the onset of muscle fatigue. Muscle fatigue was expected certainly with helmet 4, likely with helmet 3, and potentially with helmet 2 and 1. The duration of the test alone was expected to induce posterior neck muscle fatigue and affect head pitch motion. Subjects often reported fatigued necks at the end of the testing. Most subjects would stretch their neck muscles through multiple range of motion movements apparently to remove any stiffness resulting from the testing. However, the results of this test contradict the expected result. No effect of exposure duration was evident. These results suggest that aviators can maintain head pitch control independent of helmet torque for up to four hours of exposure under the conditions set by this study.

The lack of exposure duration effects allowed the pooling of the data across epoch and a subsequent multiple comparison of means test for helmet type. This showed differences among the helmets that were similar to those reported in earlier short-duration head-supported mass studies performed by the USAARL. For head pitch response, the highest torque helmet, helmet 4, was shown to be significantly different from the two lowest torque helmets, helmets 1 and 2, but not different from helmet 3. Helmet 3, the next highest torque helmet, was also found to be different from the two lowest torque helmets. Similar trends were seen for both X and Z head motion with helmet 4 being significantly

different from helmet 1. Other differences existed as shown in table 4. This result supports the recommended practice of limiting the helmet torque to 90 N·cm measured relative to the AO complex.

Head pitch response generally increased going from helmet 2 through helmet 4. This trend, however, was broken by helmet 1, which showed a pitch response averaging between the responses of helmet 2 and helmet 3. A possible explanation of this could be that helmets 2 through 4 added to the torque of the combined head-helmet system. This is the load controlled by the muscles in the neck. The added torque increased the apparent load of a mass-spring system resulting in an increase in resonant motion magnitude with an increase in helmet torque. However, helmet 1, the lowest torque helmet, actually unloaded the head-neck system. This is possible if the helmet added a negative torque measured relative to the AO complex, even though there was an overall increase in added mass. This could result in a combined head-helmet torque that was actually less than the torque created by the head alone, a torque normally controlled by the muscles of the neck. By unloading the head-neck system, the control of head pitch may become erratic resulting in an increase in resonant pitch response.

The X and Z head motion shows a decreasing response for increasing head-supported loads, as shown in figure 23 and 24.. This can be explained by recalling that head motion was calculated at the AO complex. Here the added mass is modeled as a point mass on top of the spine. By adding mass to the system, the momentum of the overall head-neck system is increased. This results in a damped X and Z motion with increased head-supported mass.

The rest break at the two-hour mark in the four-hour test is similar to the rest break aviators experience in long-duration flights when they must land and refuel. During this rest break the subjects were allowed to remove the helmet and dismount the test platform for a period of less than ten minutes. This time is thought to be long enough to experience recovery of mild muscle fatigue, preparing the subject for

the remaining two-hour test period. Though the traces of figures 19-21 are relatively flat for head motions over time, differences did occur among the helmets in the first half of the test, compared with no differences found in the second half. Recovery here would have been indicated by a restoration of these differences among the helmets. Thus there appears to be a continuation in the trends of head motion response as contrasted to any recovery effects of the rest break. If muscle fatigue occurred, that discovery will have to be the subject of other parts of the overall experimental protocol.

#### Conclusions

The results of this study investigating the effects of head-supported mass under long-duration whole-body vibration exposure indicate that there is no effect of exposure duration on head pitch, X or Z motion calculated relative to the AO complex for helmets ranging up to 90 N·cm for exposure durations of up to four hours. However, this study did show significant differences for helmet torque as measured relative to the AO complex, verifying the results of earlier short-duration studies of head-supported mass.

#### Recommendations

The practice of limiting the head-supported mass to 90 N·cm should be maintained. Future helmet designs should limit the added torque as measured in the gravity field and measured relative to the AO complex to 90 N·cm. Future studies of the effects of long-duration exposure to head supported mass should be directed towards the investigation of muscle fatigue. These biomechanical investigations coupled with investigations of psychophysical and cognitive performance can produce a head-supported mass recommended practice that is robust enough to withstand the uncertainties of future aviator crew station requirements.

## GLOSSARY

**Anatomical axes.** The X, Y, and Z-axis located in the Frankfort plane mid way between the right and left tragion. X proceeds out the bridge of the nose, Y proceeds out the left ear, and Z proceeds out the top of the head. For this study, the anatomical axes have been move to the AO complex using the same orientation, and parallel to the Frankfort plane.

**Atlanto-Occipital (AO) complex:** The pivot point of the head at the top of the cervical spine. The AO complex is a multifaceted joint involving the base of the skull or occiput, the first cervical vertebra, and the second cervical vertebra. The occiput and the first cervical vertebra create a joint that is primarily responsible for head rotation about the Y-axis, or as in nodding the head Ayes.

**Center-of-mass.** A point about which a body's linear moments sum to zero. Or the point where a body is balanced in the gravity field.

**Coordinate axis.** The reference axis will be defined as positive X forward, positive Y to the left, and positive Z vertical. Pitch is rotation about the Y-axis. Roll is rotation about the X-axis. Yaw is rotation about the Z-axis.

**External Auditory Meatus (EAM).** The external part of the ear canal; the part you can see.

**Frankfort plane.** A plane through the right and left tragion and the crest of the bony structure at the lower edge of one of the eye sockets. This defines the anatomical plane of the head.

**Head-supported mass.** A generic term describing any object supported by, or worn on, the head. Examples include a helmet, a night vision goggle, a chemical mask, oxygen mask, sun visor, etc.

**Head pitch acceleration** is rotational acceleration about the Y-axis.

**Long-duration exposure or flight.** 4 hours.

**Mass.** In a physics sense it is a measure of a body's resistance to acceleration. It is different from, but proportional to a body's weight.

**Moment.** A perpendicular force at a specified distance from a point resulting in rotational forces about that point.

**Newton-centimeter (N·cm).** Units describing a moment.

**Reference axis.** The X, Y, and Z-axis at any anatomical location, but referenced to the gravitational field where X is oriented dorsal to ventral (forward), Y is oriented lateral right to left, and Z is oriented inferior to superior (up).

**Short-duration exposure or flight.** 20 minutes.

Trigion. The fleshy knob of cartilage and skin just forward and centered on the EAM.

Weight moment. The static moment in the gravity field. A torque caused by the effect of gravity on a mass through a lever arm.

Whole-body vibration. Vibration experienced by the entire body as contrasted to segmental vibration where vibration is applied to a single point or limb. The usual input to whole-body vibration is the feet when standing, and the buttocks when sitting.

APPENDIX A  
SUBJECT BRIEFING

Safety Briefing

Mount and dismount the vibration table only when told to do so by the Safety Officer. Follow the Safety Officer's instructions at all times. This person has a safety switch that will shut down the vibration table in the unlikely event of an emergency, such as a severe vibration or jolt from the vibration table. Such an event has never occurred in the operation of the table and it is very unlikely to occur due to the many safety features of this system. If at any time you feel you want to end the testing prematurely, look at the Safety Officer and tell him that you want to stop the testing. The Safety Officer will shut down the table and you can dismount the table. Do you have any questions on the safe operation of this testing facility?

Experimental Testing

You will be asked to sit on a seat on top of a vibration platform. During the main portion of the testing, you will wear a helmet and will be exposed to four hours of whole-body vibration. The vibration you will experience is similar to that experienced by a crewmember of a US Army UH-60 helicopter.

This is a long test. There will be a 10 minute break during the at the start of the second hour of the four hour vibration exposure. Before and after the vibration, you will do a series of neck muscle exertions. During the neck muscle exertions and while you are being vibrated, myoelectric measurements will be taken from the muscles around your neck. To obtain these measurements, electrodes will be placed on your skin over six of the muscles of your neck. These electrodes measure the electrical activity in your muscles. Measurements of your

posture also will be taken during the vibration exposure. To obtain these measurements, markers will be placed on your skin and clothing. In preparation for placement of the electrodes and markers, your skin will be rubbed with an alcohol pad to remove a fine layer of dead skin. You may experience some redness due to the rubbing of your skin, but this should clear up in about a day.

During the vibration, you will be asked to sit in a relaxed posture. You will repeatedly do a series of performance tasks that vary in duration. There are three different types of performance tasks: target tracking, vigilance, and cognitive performance tests.

#### Tracking

For the tracking task, you will move your head as needed to keep the light beam mounted on your helmet on a target on a moving board in front of you. Whenever your light beam moves off the target, the amount of error will be recorded by a computer.

#### Vigilance

For the vigilance task, you will move your head as needed to locate targets in front of you when they light up. The target lights will turn off when you aim the light beam on your helmet at the target. The amount of time you take to turn off the targets will be recorded by a computer.

#### Synthetic Work Environment (SWE)

The cognitive performance task consists of four simultaneous tasks which will last for 7 minutes. The four tasks will appear on the screen of the computer placed directly in front of you and you will enter your responses using a track ball and track ball buttons. The computer will record the score, the amount of time it took you to give an answer, and whether the answer was correct. You will be required to practice these tests ten times prior to your participation in the vibration part of this effort. The four tasks are a seven letter recognition task, and auditory recognition task, a three column

addition task, and a position discrimination task. You have to do all four tasks at the same time. I will now describe these tasks.

In the seven letter recognition task, seven target letters are briefly presented in the top left of the screen at the start of the task. You must remember these letters. These letters will go away and you will be presented with a single letter. You must indicate with the track ball cursor and button if this letter is in the set of letter you saw at first. Letters will be presented during the test. You must watch for them and respond as best you can. You will be given ten points for each letter you correctly identify as being in the target set, and you will loose ten points for each letter you indicate is in the target set but is not. You must watch and listen for the other tasks while you perform this one.

In the auditory recognition task, two tones are presented: a high pitch tone and a low pitch tone. There are more low pitch tones as compared to high pitch tones. If you hear a high pitch tone you must move the cursor to the lower right of the screen and click the track ball button indicating a high pitch tone was presented. You must listen for the tones and respond as best you can. You will be given ten points for each correctly identified high pitch tone, and you will loose ten points for each low tone you identify as a high pitch tone. You must watch for the other tasks while you perform this one.

In the three column addition task, you will be required to add two numbers. You will use the track ball cursor and the buttons to create a sum. For each column, click the button to increase or decrease the sum digit. When you have completed the addition, click on the box indicating you are finished. You will receive ten points for each correct sum, and loose ten points for each wrong answer. You must watch and listen to the other tasks while you perform this one.

In the position discrimination task, you must watch a drifting bar approach one end of a region. The bar starts out at the middle of the region and will drift one way or the other. It will drift in only

one direction once it has started. The closer you let the bar get to one end of the region, the more points you will receive. You can score as many as ten points for each drifting bar. If the drifting bar reaches the end of the region, you will loose ten points. Move the cursor using the track ball and click on the reset box when you want to reset the drifting bar back to the middle of the region. You must watch and listen to the other tasks while you perform this one.

Do you have any questions on the experimental procedure?

APPENDIX C  
MULTIAxis RIDE SIMULATOR

1. The MARS consists of the following equipment:
  - a. Two large hydraulic pumps in parallel, each pumping hydraulic oil at 85 gpm at up to 3600 psi for an operating pressure of 3000 psi.
  - b. Three hydraulic accessory modules for switching the hydraulic oil flow to the actuators.
  - c. Three 13.1 kip translational hydraulic actuators each having a 3-stage valve system.
  - d. Three failsafe valves, each valve capable of shutting down oil flow to the actuators within 20 msec of the command "FAILSAFE."
  - e. One multichannel servo controller (Schenck/Pegasus 5900).
2. The MARS capabilities and specifications are as follows:
  - a. Up to 600 lbs test load, including the test subject.
  - b. Frequency response: 5 to 40 Hz, flat about  $0 \pm 1$  dB.
  - c. Up to 4 G peak acceleration.
  - d. Up to 3.5 inches peak displacement.
  - e. Failsafe shutdown occurs within 20 msec of "FAILSAFE" command from any of the following monitored parameters.
    - (1) External paddle switches.
    - (2) External safety switches on 5900 servo controller.
    - (3) AC power interrupt.
    - (4) Preset limit exceeded.
    - (5) Anticipation circuit.
    - (6) Data signal/reference signal comparison.
    - (7) Accelerometer loss.

- (8) Inner or outer loop LVDT signal loss.
- (9) Safety Officer activates failsafe switch.
3. The excitation of the MARS is accomplished as follows. A command signal is applied to the first stage of the 3-stage valve for the excited axis. The first stage consists of a force motor which is a pendulum secured within the field of the force motor transformer. When excitation is applied in the form of a command signal, the pendulum moves back and forth across two openings porting oil that is proportional to the excitation. The oil thus ported is used to move a spool valve which, in turn, ports oil at the operating pressure to move the hydraulic actuator ram. The movement of the ram is proportional in direction and phase of the excitation, and in displacement to the amplitude of the excitation.
4. Excitation to the MARS actuators is output through the multichannel servo controller from the iterated transfer function controller (ITFC) computer and created as follows. The ITFC differs from a normal control system in that the reduction of the control error is not carried out on-line, but is carried out iteratively over a specified time using the desired command signal. The actuator command signals are not corrected immediately after the occurrence of an control error. They are corrected off-line on the basis of a comparison between the recorded achieved response signals and the recorded desired response signals. The calculations of the corrected drive signals is carried out by transforming the control error with a Fourier transform and then multiplying it with the corresponding elements of an inverted frequency domain response function matrix. The result of this operation is a set of correction signals in the frequency domain that is passed through an inverse Fourier transform to create a time domain signal. This signal is weighted and added to the previous iterated drive signal. This new signal is then passed through the iterative process until the desired error limits are achieved.

5. Acquisition, identification, iteration, manipulation, and output of signals is accomplished by a set of versatile software packages run by the ITFC computer. In addition to the MARS control, the ITFC can be used to analyze test data or to generate drive signals internally. Most drive signals are provided for by sampling actual vibration signals from various ground vehicles or aircraft.

APPENDIX D  
STATISTICAL TABLES

Two way analysis of variance for epoch and helmet.

Head X motion.						
Source	Sum of Squares	DF	Mean Square	F-Ratio	P	
Epoch	0.032	15	0.002	1.086	0.366	
Helmet	0.090	3	0.030	15.278	0.000	
Epoch * Helmet	0.038	45	0.001	0.432	1.000	
Error	1.262	640	0.002			
Dep Var: Peak, N: 704, Multiple R: 0.338, Squared Multiple R: 0.144						

Two way analysis of variance for epoch and helmet.

Head Z motion.

Source	Sum of Squares	DF	Mean Square	F-Ratio	P
Epoch	0.106	15	0.007	1.782	0.034
Helmet	0.153	3	0.051	12.839	0.000
Epoch * Helmet	0.069	45	0.002	0.385	1.000
Error	2.536	640	0.004		

Dep Var: Peak, N: 704, Multiple R: 0.338, Squared Multiple R: 0.114

Significant Tukey tests comparing helmets for each epoch.

Head pitch motion.

(\* = significant differences)

Epoch	Helmet				P
	1	2	3	4	
0	*	*			0.049
0	*		*		0.012
1	*		*		0.005
2	*		*		0.029
6	*		*		0.019

Significant Tukey tests comparing helmets for each epoch.

Head X motion.

(\* = significant differences)

Epoch	Helmet				P
	1	2	3	4	
11	*		*		0.046

Significant Tukey tests comparing helmets for each epoch.

Head Z motion.

(\* = significant differences)

Epoch	Helmet				P
	1	2	3	4	
3	*		*		0.008
0		*	*		0.034

Significant Tukey tests comparing helmets, pooled across epoch.

Head pitch motion (p values).

Helmet	Helmet			
	1	2	3	4
1	1.000			
2	0.229	1.000		
3	0.034	0.000	1.000	
4	0.000	0.000	0.051	1.000

Significant Tukey tests comparing helmets, pooled across epoch.

Head X motion (p values).

Helmet	Helmet			
	1	2	3	4
1	1.000			
2	0.009	1.000		
3	0.000	0.035	1.000	
4	0.000	0.038	1.000	1.000

Significant Tukey tests comparing helmets, pooled across epoch.

Head Z motion (p values).

Helmet	Helmet		
	1	2	3
1	1.000		
2	0.710	1.000	
3	0.010	0.175	1.000
4	0.000	0.000	0.028
			1.000

INITIAL DISTRIBUTION LIST

1. Combined Arms Research Library  
U.S. Army Command and General Staff College  
1 Reynolds Ave.  
Fort Leavenworth, KS 66027-1382
2. Defense Technical Information Center  
Cameron Station  
Alexandria, VA 22314
3. David L. Bitters, Ph.D.  
DLRO  
USACGSC  
1 Reynolds Ave.  
Fort Leavenworth, KS 66027-1352
4. LTC William L. Knight, Jr.  
DLRO  
USACGSC  
1 Reynolds Ave.  
Fort Leavenworth, KS 66027-1352
5. LTC Mark D. Larson  
LID  
USACGSC  
1 Reynolds Ave.  
Fort Leavenworth, KS 66027-1352
6. MAJ Benjamin Williams III  
CTAC  
USACGSC  
1 Reynolds Ave.  
Fort Leavenworth, KS 66027-1352
7. Commander  
U.S. Army Aeromedical Research Laboratory  
P. O. Box 577  
Bldg 6901  
Fort Rucker, AL 36362-0577
8. Commander  
Armstrong Laboratories  
Biocommunications Division  
Wright-Patterson Air Force Base  
Dayton, OH 12345-6789

CERTIFICATION FOR MMAS DISTRIBUTION STATEMENT

1. Certification Date: 7 / June / 96
2. Thesis Author: Major Barclay P. Butler
3. Thesis Title: Long-Duration Exposure Criteria  
for Head-Supported Mass

4. Thesis Committee Members Signatures:

*Barclay P. Butler*  
*Barbara F. Knight Jr.*  
*Mark D. Johnson*  
*Don H. Miller*

5. Distribution Statement: See distribution statements A-X on reverse, then circle appropriate distribution statement letter code below:

(A) B C D E F X      SEE EXPLANATION OF CODES ON REVERSE

If your thesis does not fit into any of the above categories or is classified, you must coordinate with the classified section at CARL.

6. Justification: Justification is required for any distribution other than described in Distribution Statement A. All or part of a thesis may justify distribution limitation. See limitation justification statements 1-10 on reverse, then list, below, the statement(s) that applies (apply) to your thesis and corresponding chapters/sections and pages. Follow sample format shown below:

S-----	SAMPLE-----	SAMPLE-----	SAMPLE-----	S-----		
A	<u>Limitation Justification Statement</u>	/	<u>Chapter/Section</u>	/	<u>Page(s)</u>	A
M						M
P	<u>Direct Military Support (10)</u>	/	<u>Chapter 3</u>	/	<u>12</u>	P
L	<u>Critical Technology (3)</u>	/	<u>Sect. 4</u>	/	<u>31</u>	L
E	<u>Administrative Operational Use (7)</u>	/	<u>Chapter 2</u>	/	<u>13-32</u>	E
-----SAMPLE-----SAMPLE-----SAMPLE-----						

Fill in limitation justification for your thesis below:

<u>Limitation Justification Statement</u>	/	<u>Chapter/Section</u>	/	<u>Page(s)</u>
	/		/	
	/		/	
	/		/	
	/		/	
	/		/	

7. MMAS Thesis Author's Signature:

*Barclay P. Butler*

STATEMENT A: Approved for public release; distribution is unlimited. (Documents with this statement may be made available or sold to the general public and foreign nationals.)

STATEMENT B: Distribution authorized to U.S. Government agencies only (insert reason and date ON REVERSE OF THIS FORM). Currently used reasons for imposing this statement include the following:

1. Foreign Government Information. Protection of foreign information.
2. Proprietary Information. Protection of proprietary information not owned by the U.S. Government.
3. Critical Technology. Protection and control of critical technology including technical data with potential military application.
4. Test and Evaluation. Protection of test and evaluation of commercial production or military hardware.
5. Contractor Performance Evaluation. Protection of information involving contractor performance evaluation.
6. Premature Dissemination. Protection of information involving systems or hardware from premature dissemination.
7. Administrative/Operational Use. Protection of information restricted to official use or for administrative or operational purposes.
8. Software Documentation. Protection of software documentation--release only in accordance with the provisions of DoD Instruction 7930.2.
9. Specific Authority. Protection of information required by a specific authority.
10. Direct Military Support. To protect export-controlled technical data of such military significance that release for purposes other than direct support of DoD-approved activities may jeopardize a U.S. military advantage.

STATEMENT C: Distribution authorized to U.S. Government agencies and their contractors: (REASON AND DATE). Currently most used reasons are 1, 3, 7, 8, and 9 above.

STATEMENT D: Distribution authorized to DoD and U.S. DoD contractors only: (REASON AND DATE). Currently most used reasons are 1, 3, 7, 8, and 9 above.

STATEMENT E: Distribution authorized to DoD only; (REASON AND DATE). Currently most used reasons are 1, 2, 3, 4, 5, 6, 7, 8, 9, and 10.

STATEMENT F: Further dissemination only as directed by (controlling DoD office and date), or higher DoD authority. Used when the DoD originator determines that information is subject to special dissemination limitation specified by paragraph 4-505, DoD 5200.1-R.

STATEMENT X: Distribution authorized to U.S. Government agencies and private individuals of enterprises eligible to obtain export-controlled technical data in accordance with DoD Directive 5230.25; (date). Controlling DoD office is (insert).
